30 Skeletal Syndromes

Mari L. Groves, Robin Yang, and Benjamin S. Carson Sr.

Skeletal dysplasias comprise a group of disorders stemming from abnormal cartilage and bone formation, growth, and remodeling. There are more than 200 types of skeletal dysplasias, and various ways exist to characterize these disorders. They range from osteochondral dysplasias, which involve the whole skeleton, to the more limited dysostoses, which involve only a single group of bones. Skeletal dysplasias can also be categorized according to their pathogenesis as idiopathic osteolytic syndromes, primary chromosomal abnormalities, or primary metabolic abnormalities. For the purposes of this review, we concentrate on achondroplasia because it is the most common skeletal dysplasia that requires neurosurgical intervention. Other skeletal dysplasias that sometimes require neurosurgical intervention are addressed at the end of the chapter.

Achondroplasia is an autosomal-dominant disorder that affects the fibroblast growth factor receptor 3 (*FGFR3*) gene. This phenotype leads to disproportionately short stature with rhizomelic shortening of the extremities that results from the defective formation of endochondral bone.¹⁻³ Spontaneous mutations account for 70% of cases. Rare cases of homozygous achondroplasia are uniformly fatal primarily because of chest cavity restriction. Achondroplasia occurs in 1 in every 26,000 to 28,000 births, with an incidence of 0.03 to 0.05% of all live births.^{1,2,4} Bony compression of the neuraxis and respiratory failure are the primary sources of morbidity in achondroplasia.⁵⁻⁷ Most individuals with achondroplasia are of normal intelligence; however, their motor milestones may be delayed, partly because of the mechanical limitations of their short limbs and occasionally because of generalized hypotonia.⁸

Patients with achondroplasia present to neurosurgeons with three varying types of symptomatology: hydrocephalus, cervicomedullary compression, and spinal stenosis. Hydrocephalus and cervicomedullary compression present in infancy and childhood⁹ (► Table 30.1). Respiratory symptoms result from both mechanical obstruction and physical restriction. Upper small airway disease results in obstructive sleep apnea and manifests as snoring.¹⁰ Many infants compensate by hyperextending their necks during sleep to overcome this obstruction. However, extension of the neck exacerbates the small foramen magnum and cervicomedullary compression.¹¹ A smaller thoracic cavity can also result in restrictive symptoms, which may lead to respiratory compromise. This can be further compounded by gastroesophageal reflux, aspiration, and recurrent pneumonias. Spinal stenosis typically presents in young and middle adulthood. These patients present with neurogenic claudication, back pain, and occasionally urinary and bowel incontinence. We discuss further the work-up and management of patients who have achondroplasia with cervicomedullary compression and spinal stenosis.

30.1 Indications for Surgical Treatment

30.1.1 Cervicomedullary Compression

Patients with achondroplasia have neurologic manifestations in 35 to 47% of cases. They also have increased age-adjusted mortality rates at all ages, with the highest occurring in childhood. Foramen magnum stenosis is a common radiologic finding, but this does not always corroborate with the clinical symptoms. In a prospective evaluation, Pauli and colleagues studied 53 infants with achondroplasia.¹² More than 70% of the children had foramen magnum stenosis or associated craniocervical abnormalities on magnetic resonance (MR) imaging. However, only 14% of them developed clinical symptoms necessitating surgical decompression.¹² In an additional study, Reid and colleagues found evidence of foramen magnum stenosis in 60% of prospectively evaluated patients with achondroplasia, but only 35% demonstrated clinical symptoms of cervicomedullary compression.¹³

Foramen magnum stenosis results from defective endochondral bone growth and an abnormal fusion pattern of the posterior basal synchondrosis.^{4,14} The foramen magnum is formed by the exoccipital, supraoccipital, and basioccipital bones, which enlarge by endochondral ossification in cases of achondroplasia.¹⁵ The result is a small foramen magnum, short basicranium and clivus, shallow posterior fossa, horizontally oriented inferior occiput, abnormal odontoid process, stenotic jugular

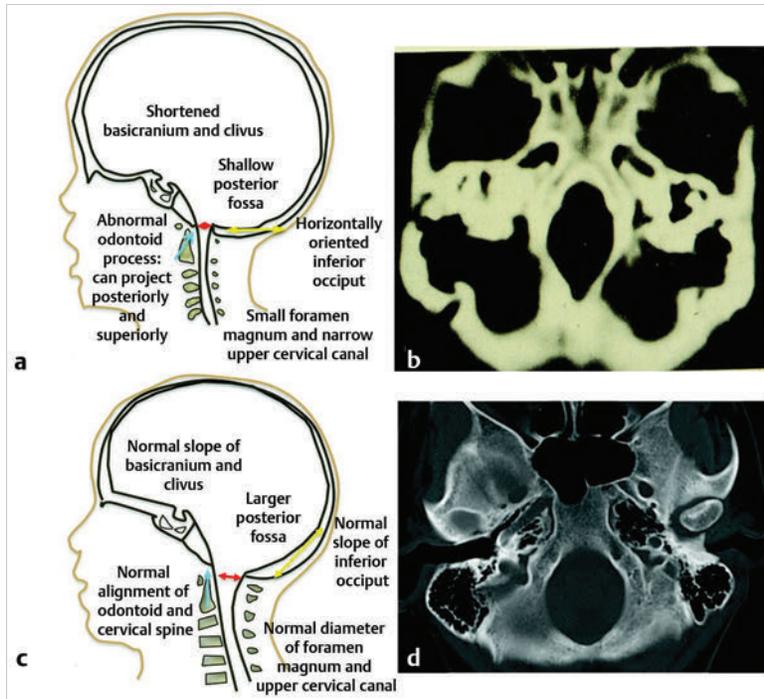

Fig. 30.1 Comparative foramen magnum anatomy in a patient with achondroplasia (a, b) and a normal person (c, d). Reduction in the sagittal and coronal dimensions of the foramen magnum leads to cervicomedullary compression (a). The cranial base is derived from endochondral ossification, which is not normal in achondroplasia. As a result, the base is stunted, shorter, and narrower than normal. The basioccipital bone is narrow and angulated, and the lateral and posterior parts have similarly abnormal characteristics that result in a diamond, triangular, or teardrop-shaped foramen magnum (b) in comparison with a normal skull base (d). The posterior fossa is small because the occipital bone is horizontally angled. This causes stenosis of the foramen magnum and cervical canal (a), which pushes the brainstem upward and applies pressure on the brainstem and upper cervical spinal cord.

foramina, and narrow upper cervical canal^{2,4,16} (► Fig. 30.1). These patients also have premature fusion and aberrant development of the two posterior synchondroses, which contribute to the stenosis and thickening of the foramen magnum rim.^{2,16} This can project into the brainstem and cervical canal. Further narrowing of the foramen magnum results from abnormal fusion of the posterior neural arch of the atlas with the posterior foramen magnum, as well as from dense fibrotic epidural bands found anterior to the posterior ring of the atlas.¹⁴ The odontoid process also can project posteriorly and superiorly, resulting in medullary compression.^{15,16}

Compression of the cervicomedullary junction can manifest as lower brainstem and high cervical spine compression leading to myelopathy, hydrocephalus, respiratory compromise, and sudden death. Young infants may have subtle findings but can have excessive hypotonia, poor head control, feeding or sleep difficulties, and apnea. Most patients with achondroplasia exhibit hypotonia during early infancy and can exhibit developmental delay in achieving motor milestones regardless of hydrocephalus.³ However, they typically catch up to normal children by the age of 2 to 3 years. Sudden death in infants with achondroplasia is the most feared complication of cervicomedullary compression. Hecht and colleagues reviewed a cohort of 781 individuals with achondroplasia and found a 7.5% risk for sudden death within the first year and a 2.5% risk for sudden death between 1 and 4 years of age.¹⁷ A retrospective analysis by Pauli and colleagues studied 13 patients with a sudden unexplained death or apnea. Of these patients, five had evidence of acute or chronic compression of the medulla and spinal cord at autopsy.¹⁸ Other postmortem studies have found similar cystic degenerative changes in the lower brainstem and syrinx formation of the upper cervical cord, concerning for chronic compression of the cervicomedullary junction.¹² Apnea may result from damage to respiratory control centers in the medulla,

compression of lower motor neurons that innervate the diaphragm and accessory muscles, and nonneurologic causes including upper airway obstruction, small thoracic cage, and mid-face hypoplasia.^{14,20–22}

There are two prevailing hypothesis for hydrocephalus in children with achondroplasia. The first attributes hydrocephalus to foramen magnum stenosis that leads to obstruction of the cerebrospinal fluid (CSF) outflow pathways, and the second attributes it to increased intracranial venous sinus pressure caused by compression at the jugular foramen. Yamada and colleagues favor the hypothesis of compression at the foramen magnum.¹⁵ However, patients have been noted to have relatively normal intracranial pressure (ICP) despite radiologic evidence of ventriculomegaly.¹⁶ Steinbok and colleagues found that raised intracranial venous pressure was secondary to stenosis of the jugular foramen, and occasionally of the jugular vein in the thoracic aperture.²² Treatments to consider include ventriculoperitoneal shunt and jugular foramen decompression, as these address the underlying etiology of the hydrocephalus. However, if the patient does not demonstrate signs of increased ICP, including headaches, lethargy, poor feeding, and irritability, therapy can be delayed as ventriculomegaly often abates with time.^{4,16}

Surgical intervention is based on signs or symptoms of neurologic dysfunction, not exclusively on radiologic imaging. Clinical signs such as apnea, lower cranial nerve palsies, hyperreflexia, sustained clonus, and weakness should be considered markers of cervicomedullary compression. Imaging findings that are suggestive of foramen magnum compression include intramedullary spinal cord changes on T2-weighted magnetic resonance (MR) imaging, lack of CSF flow anteriorly or posteriorly at the foramen magnum, and the presence of a syrinx (► Fig. 30.2). In a prospective analysis, Pauli and colleagues determined that lower limb hyperreflexia or clonus, central hypopnea on polysomnography, and foramen magnum

measurements lower than the mean for children with achondroplasia are the best signs and symptoms for predicting the need for surgical decompression.^{12,18}

30.1.2 Spinal Stenosis

The abnormal anatomical architecture of the achondroplastic spine contributes to both spinal cord and nerve root compression. The vertebral bodies have a classic mushroom shape on contrast myelograms secondary to hypertrophy of the superior and inferior articular facets.²³ Premature fusion of the centers of ossification of the vertebral bodies and the posterior neural arches results in laminae and pedicles that are short and thick. Posteriorly, the vertebral bodies assume a concave curvature. The consequence of this curvature can be improper projection

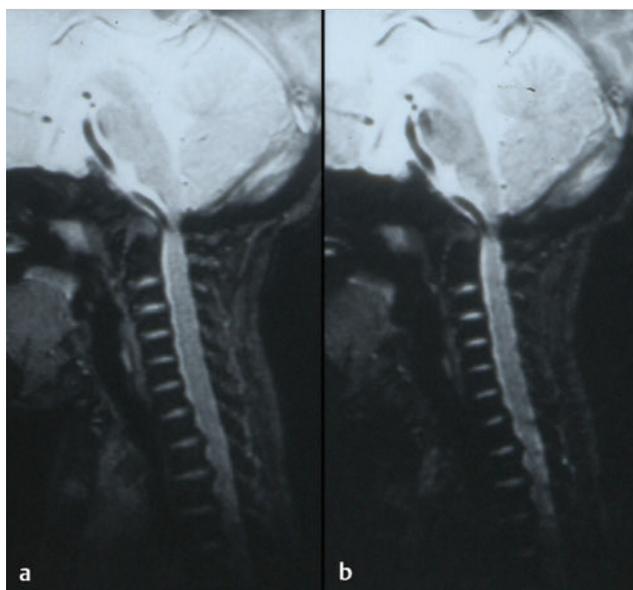

Fig. 30.2 (a) Sagittal T2-weighted magnetic resonance images showing a lack of cerebrospinal fluid flow anteriorly or posteriorly at the level of the foramen magnum. (b) The cervical canal also shows signs of congenital stenosis and a loss of normal lordosis.

of the inferior and superior ends into the spinal canal that further compromises the spinal subarachnoid space.²⁴ The overall scenario results in dramatic stenosis in every anatomical dimension of the spine (► Fig. 30.3).

Neurologic problems located below the foramen magnum often present later in adolescence. However, in one series of patients, symptomatic stenosis was seen 35% of the time in patients before the age of 15 years.²⁵ It is estimated that anywhere from 30 to 89% of patients with achondroplasia eventually experience symptoms associated with spinal stenosis. Children and adults typically present with multisegmental spinal stenosis involving the subaxial cervical or thoracolumbar spine. It is important to distinguish between the neurosurgical and the orthopedic characteristics for the management of the achondroplastic spine. Neurologic symptoms result from narrowing of the spinal canal due to a shortened pedicle length and small interpedicular distance. Orthopedic concerns result from patient issues such as physical limitations of the chest cavity and rotund abdomen, which tend to favor the formation of a progressive kyphosis.^{26,27} Some authors even discourage early ambulation and “sitting up” in these patients to minimize aggravation of their thoracolumbar kyphosis.⁸ In addition, hypotonia may prevent adequate protection of the skeletal structures in weight-bearing postures.⁹ Full-time bracing may be indicated if the kyphosis does not resolve by the age of 3 years, and if this fails to halt the progression of kyphosis, surgery can be indicated. Secondary instability can lead to worsening kyphosis or spinal deformity and is addressed in further detail below.

The evaluation of these patients in more advanced cases can reveal neurologic abnormalities, such as weakness of the lower extremities and hypoesthesia. Coexistent cervical and thoracic compression presents as spasticity and hyperreflexia of the lower extremities. Imaging should include both MR imaging and computed tomography (CT) for assessment and perioperative planning. MR imaging more frequently demonstrates disk pathology and any associated soft tissue hypertrophy (► Fig. 30.4). CT myelography has the advantage of revealing any regions of compression due to hypertrophy and providing information distal to the level of complete spinal block.

Urgent surgery is indicated for those patients who have neurologic impairments such as urinary incontinence or urgency, bowel incontinence, and worsening weakness that can

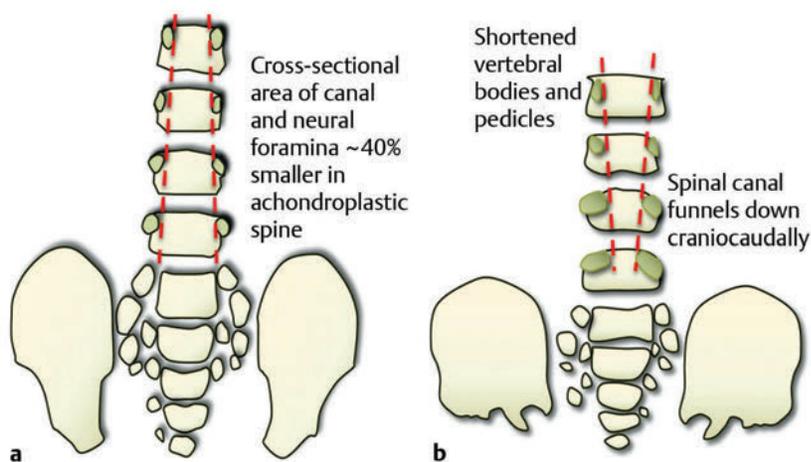

Fig. 30.3 Anatomical representation of a normal (a) and achondroplastic (b) spine. The anatomical architecture of the achondroplastic spine contributes to spinal cord and nerve compression, with hypertrophy of the superior and inferior articular facets, which show a classic mushroom shape on a computed tomographic myelogram. Premature fusion of the centers of ossification of the vertebral bodies and the posterior neural arches results in shortened and thickened laminae and pedicles. Additionally, the pedicles grow larger more caudally, and as a result, the spinal canal narrows in the lumbar region.

Fig. 30.4 Sagittal T2-weighted magnetic resonance (MR) image showing lumbar stenosis. MR imaging can more frequently demonstrate disk pathology and any associated soft-tissue hypertrophy. Posteriorly, the vertebral bodies assume a concave curvature that results in improper projection of the inferior and superior ends into the spinal canal.

be attributed to compression of the cord or cauda equina. Surgery should also be considered for patients with back pain secondary to stenosis, depending on how this affects their quality of life.²⁷ Decompressive laminectomies are indicated for patients whose ambulation is hindered by claudication and significant weakness at rest. Preoperative urologic testing should be performed as part of the work-up for a laminectomy, given the high rate of urinary incontinence that can result from surgery. This would include a urinalysis, urine culture, and urodynamic study to assess bladder compliance.

30.2 Surgical Treatment

30.2.1 Cervicomedullary Compression

Foramen magnum decompression is recommended early in the course of symptomatic cervicomedullary compression because

it has been shown to significantly improve outcome for these patients.^{7,28,29} An approach similar to the decompression of a Chari malformation can be utilized, which includes a suboccipital craniectomy and removal of the posterior arch of the atlas; however, the unique anatomy present in patients with achondroplasia must be taken into consideration during operative planning.

Patients are positioned prone on the operative table in slight flexion to minimize significant compression of the airway as well as to limit the subarachnoid space at the foramen magnum. Preoperative steroids are given to protect the spinal cord and brainstem from local trauma. The patients are followed with somatosensory evoked potentials (SSEPs) to assess for dorsal column injury. A midline suboccipital incision is made, and the posterior ligaments and paraspinal musculature are dissected subperiosteally to expose the occiput, spinous processes, and laminae of C1 and C2. The posterior arch of C1 is then removed with a high-speed drill. If there is significant compression further caudally, then the laminae of C2 must also be decompressed. The bone of the foramen magnum is thickened and oriented more horizontally than in typical pediatric patients and can indent the underlying dura. This angle can be assessed through preoperative imaging. The posterior rim of the foramen magnum should be gradually thinned and removed with small curets. There is typically a thick, fibrous band, or pannus, extending from the foramen magnum to C1 that should be left in place during the initial bony decompression to help protect the underlying dura. The most critical part of the bony decompression is removing the lip of the foramen magnum as this can be surrounded by the dura, making it difficult to remove without a durotomy.

Once the bony decompression is completed, the fibrous band can be removed. A transverse dural channel will indicate how restricted the dura was before decompression. The dura is often fused with this soft tissue band, and the annular sinus is commonly insinuated throughout the dura. If the band and dura are difficult to divide, then duraplasty should be performed in order to ensure removal of the compression. Duraplasty should also be performed if there is a persistent dural constriction after removal of the fibrous band. Intraoperative ultrasound should be used to confirm adequate cord pulsation and CSF flow. After duraplasty, a dural patch of pericranium, paraspinal fascia, or cadaveric dura is inserted to provide extra room at the foramen magnum. A watertight seal is essential as many of these patients have increased ICP and are at risk for the development of a CSF leak and possible pseudomeningocele. A ventriculostomy can be performed if there is preoperative concern for increased ICP or hydrocephalus that might complicate wound closure. Wound drains are not recommended as these can potentiate the development of a CSF fistula. Intraoperative SSEPs are critical throughout the procedure, and improvement will often be seen following decompression and restoration of CSF flow. Following the procedure, the surgeon should confirm movement in all four extremities before extubation. If there is a concern for a neurologic change, there may be damage to the underlying brainstem, and the patient should remain intubated until the respiratory drive and ability to ventilate are well established. Postoperatively, the patient should be monitored in an intensive care unit for any respiratory compromise or evidence of elevated ICP.

There are several points of difference between this procedure and a traditional decompression of the posterior fossa. The foramen magnum and posterior arch of C1 provide extensive constriction and pressure over the cervicomedullary junction. Introduction of even the smallest instrument can transmit significant pressure and compression to the underlying brainstem and spinal cord, and thus the surgeon should avoid placing any instruments, curets, or Kerrison rongeurs in this area. Patients with achondroplasia also have a relatively small posterior fossa with a small underlying brainstem and spinal cord, and therefore they do not need as large a decompression. The surgeon should have an appreciation for the actual size of the underlying neural elements and tailor the decompression to the appropriate size. The decompression should encompass the dorsal surface of the cervicomedullary junction along the lateral dimensions of the medulla in order to adequately decompress the stenosis at the level of the foramen magnum. This general area can be estimated by reviewing the preoperative MR imaging.

Patients with achondroplasia may also have significant engorgement of the veins lying below the ligamentum flavum both dorsally and laterally. These can be the source of significant bleeding, which must be rapidly controlled if they are entered. Air embolism can result from a tear in these venous structures, and the surgeon should ensure the patient is placed in the Trendelenburg position if this occurs and continue irrigation and packing of the area.

30.2.2 Spinal Stenosis

Patients with achondroplasia typically have a significant extent and severity of spinal stenosis. Historically poor operative results were obtained before the advent of CT and MR imaging as the degree of stenosis was often underappreciated.³⁰⁻³² Bulky instruments were used for decompression, and this frequently traumatized the underlying spinal cord and nerves. Postoperative instability was common, given the overly wide laminectomies performed for the size of the spinal canal.³²⁻³⁴ Review of the preoperative MR images and CT scans will show the degree of stenosis. If it is not clear, myelography can sometimes be used as an adjunct to show the level of stenosis, although it may not estimate the rostral to caudal length of spinal stenosis. The surgeon should be prepared with an operative plan that includes decompression of more than one or two segments above the level of the block and the same below.²⁵ Pediatric patients are more likely to require fusion in the future because the immature spinal canal has a greater propensity toward instability and deformation,³⁵ and thus we recommend a fusion procedure for any decompression of more than five levels and for any decompression crossing the thoracolumbar junction.

The patient should be in the prone position, and perioperative steroids should be given in a similar manner to that previously described. These patients should also be monitored for SSEP changes throughout the course of the procedure. A posterior midline incision is made, and dissection of the paraspinal musculature is carried out in a subperiosteal fashion to expose the spinous processes, laminae, and facet joints over the area of decompression. The laminae medial to the facet joints should be thinned with a high-speed drill or BoneScalpel (Misonix, Farmingdale, NY) to form a trough parallel to the longitudinal axis of the spinal column. The drill head should be pointed

toward the facet at approximately a 45-degree angle, which helps the surgeon maintain adequate control and avoid dural tears below. The groove is then thinned until the dura can be seen through the laminar mantle. This should be replicated on the opposite side for the length of the planned laminectomy. After the bone has been adequately thinned, a small dural patch can be inserted into the epidural space without significant compression on the spinal canal below. More recently, we have started utilizing the BoneScalpel (Misonix, Farmingdale, NY) which performs precise osteotomies through longitudinal ultrasonic oscillations. The device selectively impacts bone more than the surrounding soft tissue, and its blunt tip helps protect the underlying dura from trauma. We use this device to create bilateral troughs and can then remove the laminae en bloc without significant neural trauma. If the facet joints are violated throughout any part of this procedure, stabilization through spinal fusion becomes necessary. A retrospective analysis from our institution showed that children with achondroplasia and symptomatic stenosis were at high risk for progression to kyphotic deformity if more than five levels were removed through laminectomy.

Removal of the bony architecture in addition to dissection of the paraspinal musculature creates a deep void, especially at the lumbosacral junction. To avoid pseudomeningocele formation, a multilevel closure is performed to reapproximate the muscle masses and fill the dead space.³⁶ A paraspinal muscle encased in fascia is detached from the iliac spine and the lumbosacral laminae and reflected around its pedicle. The edge of the flap is brought down to the opposite lateral end of the laminae and is attached with resorbable sutures along the inferior part of the paraspinal muscles (► Fig. 30.5). The superior part of the muscle mass is then retracted over the first flap, thus completing the muscle closure and collapsing the void.

30.3 Treatment Alternatives

30.3.1 Cervicomedullary Compression

Traditionally, duraplasty has been offered to patients with achondroplasia for a more extensive decompression of the brainstem. However, in our institution, we have moved away from automatically performing a duraplasty unless adequate CSF flow is not restored following bony decompression and release of the fibrous band. As a result, the vast majority of our patients do not require duraplasty. Ultrasound is critical to demonstrate free movement of the brainstem and cerebellum.

30.3.2 Spinal Stenosis

Some investigators will argue that performing a wide decompression by undermining the facets and performing foraminotomies is necessary to adequately decompress the spinal cord and nerves.³⁵ However, in our experience, the lateral recesses in the patient with achondroplasia are relatively small, and we have not had a significant benefit in undermining the facets. Additionally, wider laminectomies are more destabilizing, and these patients go on to require more extensive surgeries in the future as a result. Spinal fusion should be considered up front for those patients undergoing extensive laminectomies of more than five levels.

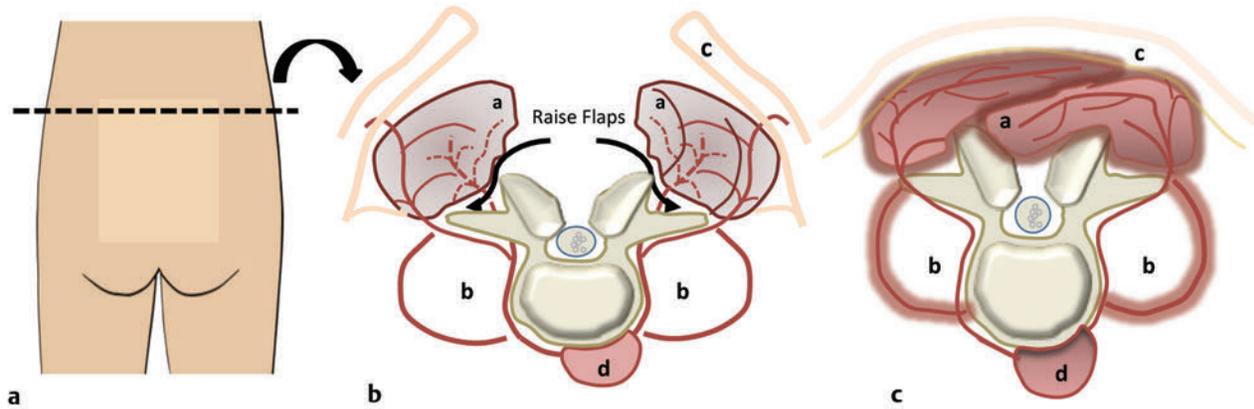

Fig. 30.5 Cross section of the lumbar spine (a) that depicts elevation of a paraspinous muscle flap (b). The paraspinous musculature (a) is released from any lateral attachments and reflected to cover the resultant laminectomy defect and any associated spinal hardware (c). Attaching the paraspinous muscles to each other is important to help fill the dead space over the dura. The psoas muscle (b), skin flap (c), and medial and lateral paraspinous perforator arteries originate from the posterior intercostal artery, which in turn originates from the aorta (d). Hydrocephalus and cervicomedullary compression present earlier, in younger patients, than spinal stenosis and back pain.

30.4 Prognostic Factors and Outcomes

30.4.1 Cervicomedullary Compression

Patients with symptomatic cervicomedullary compression usually show marked immediate improvement in their neurologic function after a successful decompression. In 2006, Bagley and colleagues reported on a series of 43 pediatric patients with symptomatic achondroplasia who underwent cervicomedullary decompression over an 11-year period. Most of their patients had sleep apnea or respiratory symptoms. All patients showed significant improvement of their respiratory symptoms after decompression.² There was no mortality, and the most common surgical morbidity was CSF leak in patients who had a durotomy. This was successfully managed by either reinforcement of the wound or CSF diversion in all cases. In another series, Aryanpur and colleagues reported on 14 pediatric patients with achondroplasia and cervicomedullary compression.²¹ Six of eight patients with apnea or cyanosis had total resolution of the issues after decompression. Nine of ten patients had improvement or resolution of their paresis, hyperreflexia, or hypertonia.²¹

A larger study, in which the 36-Item Short-Form Health Survey from the RAND Medical Outcomes Study was used, compared a total of 122 patients. A group of 66 patients with achondroplasia who were asymptomatic were compared with 56 patients who underwent decompression for symptomatic craniomedullary compression. The study showed that quality-of-life measures were not significantly different between the two groups, suggesting that despite undergoing surgery, patients with achondroplasia maintain a quality of life similar to that of patients who are followed with conservative management.³⁸

30.4.2 Spinal Stenosis

The treatment of spinal stenosis with surgical intervention has yielded mixed results.^{17,35} In the general population, multiple studies have concluded that time from onset of symptoms to laminectomy is a significant prognostic indicator of improvement.^{39,40} The importance of this prognostic factor has not fully been quantified in the prospective literature in regard to the pediatric population with achondroplasia. In 2011, Carlisle and colleagues described their experience with laminectomies in patients with achondroplasia at The Johns Hopkins University.³⁹ They showed that patients with a “time-to-surgery” interval of less than 6 months were seven times more likely to experience improvement in their walking distance and four times more likely to have Rankin Scale improvements than patients who had symptoms for more than 6 months.⁴² As with cervicomedullary decompression in patients with achondroplasia, it may be beneficial to recognize that earlier neurosurgical evaluation is needed because of the narrow therapeutic window before the development of permanent neurologic sequelae.

Spinal stenosis is more frequently encountered than cervicomedullary compression in patients with achondroplasia, and laminectomy provides adequate decompression for symptomatic patients. The morbidity associated with this procedure is higher in patients with achondroplasia than in the general population. In 1990, Uematsu reported a retrospective analysis of 67 patients over a 10-year period and found an improvement in symptoms in 70% of patients who underwent thoracolumbar decompression. Of the remaining patients, 22% experienced deterioration and 8% showed no symptomatic change. Intraoperatively, these patients were more likely to have durotomies (43%) because the dura is thinner in patients with chronic stenosis than in a normal adult population. Outcomes were quantified

with a functional rating scale and a comparison of functional assessments pre- and postoperatively. The best predictor for improvement following surgery was a shorter duration of symptoms before surgery. Urinary retention was the most common postoperative complication and developed in 38% of patients with spinal stenosis. Other complications included wound infection (13.5%) and pseudomeningocele that required operative repair (10%).⁴¹

Ain and colleagues published their series of postlaminectomy kyphosis in the thoracolumbar region in 10 patients with achondroplasia who underwent decompression for stenosis. They found that despite multilevel decompression, more than 50% of each medial facet was preserved in these patients that aided in maintaining spinal stability. However, all of the patients went on to develop kyphosis and subsequently underwent spinal fusions with instrumentation within 2.6 years of their original surgery. They recommended concurrent spinal fusion in patients undergoing at least five levels of laminectomy given the high risk for postlaminectomy thoracolumbar kyphosis.³⁵ A subsequent study also recommended spinal fusion in patients with a large decompression overlying a thoracolumbar kyphosis to avoid progressive postoperative deformity.⁴⁴

Baca and colleagues retrospectively reviewed a series of patients who underwent decompression for lumbar stenosis.⁴² Of the 18 patients studied, 9 had a fusion procedure at the time of their initial surgery and 9 did not. Only 2 patients from the fusion group required revision surgery during the follow-up period, whereas 7 of the patients who did not have fusion initially later required revision surgery (22% vs. 78%).⁴² Sciubba and colleagues reported their series of 44 patients and found that 72% of patients who underwent decompression also had fusion at the time of their surgery.⁴⁰ In the patients who underwent revision surgery, the thoracolumbar junction was at highest risk for junctional stenosis, and as a result, a fusion procedure is recommended when the area of decompression traverses the thoracolumbar junction.

30.5 Complications

The most common complication associated with craniocervical decompression is a CSF leak from the suboccipital incision or the site of a previously placed shunt. The reported CSF leak in the literature ranges from 15 to 25%.^{2,22} Foramen magnum decompression can be performed with an expected low rate of morbidity and can provide excellent clinical benefit.

Hydrocephalus and increased ICP are a concern in these patients as change in the bony anatomy predisposes them to higher-than-normal ICP and hydrocephalus. Following decompression, patients who had severe respiratory and neurologic disease can make significant developmental strides and experience resolution. One past series has shown an increased rate of shunt placement following cervicomedullary decompression.⁴³ The etiology behind increased ICP in patients with achondroplasia is unclear, but venous hypertension has been thought to play a role. However, our experience has shown that patients undergoing cervicomedullary decompression do not have a high rate of secondary shunt dependency following their procedure.⁴¹

Despite adequate decompression in spinal stenosis, restenosis may occur because of accelerated facet hypertrophy, bony overgrowth, and scarring. This may be due to instability in the spine or an exaggerated response to normal motion resulting from some interaction of the genetic components of the disease. Several series have shown that reoperation was necessary for achondroplastic spinal restenosis.³⁵ In one series, the reoperation rate was 4.3% for all patients with achondroplasia undergoing spinal decompression. The most common causes of recurrent stenosis were facet hypertrophy (75%), disk pathology (50%), bony overgrowth (37.5%), kyphosis (37.5%), spur formation (25%), and fusion construct (12.5%).⁴¹ Repeated surgery carried a higher risk for dural tear than the initial procedure. Destabilization due to a more expansive bony decompression that subsequently required fusion occurred in 50% of the cases. Despite the higher risk for morbidity and the possible need for fusion, 75% of the patients showed postoperative improvement in their strength.⁴³

30.6 Other Skeletal Dysplasias

Although in this chapter we have concentrated on the neurosurgical presentations associated with achondroplasia, there are other skeletal dysplasias that require neurosurgical evaluation. We briefly discuss both the congenital and genetic manifestations of the skeletal dysplasias commonly seen in the pediatric population (► Table 30.2).

Down syndrome is one of the more common congenital disorders arising from trisomy of chromosome 21. Cervical spine instability resulting from laxity of the ligaments surrounding the odontoid process is well documented.^{44–46} Radiologic instability identified from measurements of the atlantodental interval is seen in 10 to 30% of patients,^{44–47} but only approximately 1% of patients have symptomatic C1–C2 instability that warrants operative treatment. Osseous abnormalities including os odontoideum, odontoid hypoplasia, ossiculum terminale, and rotary atlantoaxial subluxation are also common and can contribute to instability.^{44,46} In addition, children with Down syndrome have occiput–C1 joint instability due to architectural changes in their bone that can be seen in 40 to 50% of patients with symptomatic craniovertebral abnormalities.^{44,45,50} Surgical treatment is recommended for any patient with more than 8 to 10 mm of subluxation at the occiput–C1 level.^{48,49,54}

Neurofibromatosis type 1 is an autosomal-dominant neurocutaneous syndrome that arises from a mutation in the *NF1* tumor suppressor gene located on chromosome 17. Among other findings, approximately 10 to 20% of children present with scoliosis.⁵¹ It has been suggested that this arises because of mesodermal dysplasia, endocrine disturbances, or in some cases osteomalacia arising from infiltration of bone by neurofibromas.⁵⁵ Dystrophic scoliosis may progress to kyphoscoliosis. Kyphoscoliosis involves dysplastic changes in the spine, with deformed vertebral bodies and an acute anteroposterior angulation resulting in neurologic impairment in some cases.

Osteogenesis imperfecta is a congenital disorder arising from a mutation in a gene for collagen turnover. It is associated with osteopenia and fragile bones that are susceptible to fracture. These patients have short stature and progressive skeletal

Table 30.2 Some of the more commonly presenting syndromes evaluated by neurosurgeons for surgical intervention

Skeletal dysplasia	Etiology	Physical findings	Neurologic findings
Achondroplasia	Autosomal-dominant missense mutation in <i>FGFR3</i>	<ul style="list-style-type: none"> • Short stature with rhizomelic shortening of the extremities • Macrocephaly with frontal bossing • Midface hypoplasia 	<ul style="list-style-type: none"> • Foramen magnum stenosis • Spinal canal stenosis • Hydrocephalus
Down syndrome	Trisomy of chromosome 21	<ul style="list-style-type: none"> • Low muscle tone • Flat facial features • Upward eye slant with abnormally shaped ears • Hyperflexibility • Hyperglossia 	<ul style="list-style-type: none"> • Cervical instability secondary to laxity of ligaments surrounding odontoid process • Craniovertebral abnormalities with occiput-to-C1 joint instability • Abnormalities of odontoid (os odontoideum, hypoplasia, ossiculum terminale, rotatory atlantoaxial subluxation)
Neurofibromatosis type 1	<i>NF1</i> tumor suppressor gene on chromosome 17	<ul style="list-style-type: none"> • Lisch nodules • Bone deformities • Café au lait spots and skin freckling • Neurofibromas • Short stature and large head size 	<ul style="list-style-type: none"> • Scoliosis from mesodermal dysplasia or endocrine disturbances, or osteomalacia from bony infiltration of neurofibromas • Neurofibromas • MSNPT
Osteogenesis imperfecta (types 1–4)	Mutation in <i>COL1A1</i> or <i>COL1A2</i> leading to decreased amount of collagen turnover	<ul style="list-style-type: none"> • Risk for bony fractures • Short stature • Progressive skeletal deformities 	<ul style="list-style-type: none"> • Kyphosis and scoliosis • Risk for compression fractures and vertebral body collapse • Basilar impression
Goldenhar syndrome (oculoauriculovertebral dysplasia)	Disruption in development of first and second branchial arches during the first 6 weeks of embryogenesis	<ul style="list-style-type: none"> • Craniofacial deformities (cleft lip) • Congenital heart defects • Hemifacial microsomia 	<ul style="list-style-type: none"> • Spinal anomalies (vertebral hypoplasia, failure of segmentation, failure of vertebral formation) leading to thoracolumbar kyphosis with segmentation anomalies • Spina bifida occulta • Sacral agenesis

Morquio syndrome (mucopolysaccharidosis type 4)	Autosomal-recessive lysosomal storage disease leading to inability to mobilize keratin sulfate	<ul style="list-style-type: none"> • Pectus carinatum • Thoracolumbar kyphosis and scoliosis • Genu valgum • Platyspondylia • Joint hypermobility 	<ul style="list-style-type: none"> • Atlantoaxial subluxation arising from odontoid dysplasia and ligamentous laxity
Larsen syndrome	Autosomal-dominant mutation in <i>FLNB</i> (filamin B)	<ul style="list-style-type: none"> • Hypermobility • Congenital dislocations • Brachycephaly • Cleft palate 	<ul style="list-style-type: none"> • Spinal deformities with flattened or hypoplastic vertebral bodies or posterior elements • Dysraphism and hemivertebrae • Absence of pedicles leading to dislocation

- Abbreviation: MSNPT, malignant peripheral nerve sheath tumor
- Note: More than 200 types of skeletal dysplasia have been described.

deformities. In some series, up to 80% of patients develop kyphosis and scoliosis that progress despite bracing.^{52,53} Patients with more severe cases (types 3 and 4) are too fragile to withstand any surgical intervention. These patients are also at risk for compression fractures and vertebral body collapse, as well as basilar impression.

Goldenhar syndrome, or oculoauriculovertebral dysplasia, is a heterogeneous disorder that is attributed to a disruption in development of the first and second branchial arches during the first 6 weeks of embryogenesis. Spinal anomalies include vertebral hypoplasia, failure of segmentation, and failure of vertebral formation that then lead to thoracolumbar kyphosis with segmentation anomalies. These patients can also present with block vertebrae, unilateral hemivertebrae, spina bifida occulta, butterfly vertebrae, and sacral agenesis.⁵⁵

Spondyloepiphyseal dysplasia encompasses several disorders arising from abnormal growth of the spinal vertebrae and epiphyses. These patients have short-trunk dwarfism, and severe spinal abnormalities are associated with the congenital form of the disorder. Patients develop atlantoaxial instability due to odontoid hypoplasia or ligamentous laxity that puts them at risk for spinal compression.⁵⁶

Morquio syndrome, or mucopolysaccharidosis (MPS) type 4, is an autosomal-recessive lysosomal storage disease characterized by an inability to metabolize keratan sulfate. These patients have short-trunk dwarfism with skeletal features that include pectus carinatum, thoracolumbar kyphosis, scoliosis, genu valgum, platyspondylia, flaring of the ribs, and joint hypermobility.⁵⁷ The most common spinal manifestation is atlantoaxial subluxation (42 to 90%) arising from odontoid dysplasia and ligamentous laxity that then leads to spinal cord compression.^{58,59}

Larsen syndrome is a rare congenital disorder of connective tissue that is associated with deformities of the spine: flattened or hypoplastic vertebral bodies or posterior elements, dysraphism, hemivertebrae, and wedged vertebrae.^{60,61} These patients also can develop progressive kyphosis and even anterior posterior dislocation due to an absence of pedicles. Cervical kyphosis is the most common deformity, occurring in approximately 12%, and can lead to quadriplegia and death.⁶⁰ Patients with Larsen syndrome are at risk for thoracic insufficiency syndrome secondary to the scoliosis that deforms the rib cage and limits adequate ventilation. There is a 40% rate of mortality due to respiratory complications.⁶² As a result, preoperative assessment of the patient's pulmonary function is essential and can include pulmonary function tests and bronchoscopy in addition to CT. Cervical spine kyphosis and subluxation should be treated with decompression and fusion before any correction of the scoliosis is undertaken given the concern for compression of the cervical spine. The progressive scoliosis can be addressed with one of the growth-sparing procedures that range from growing rods if there is minimal thoracic deformity to a VEPTR (vertical expandable prosthetic titanium rib) expansion thoracoplasty if there is significant thoracic deformity.⁶²

30.7 Conclusion

Skeletal dysplasias are a complex group of diseases affecting the bone or cartilage that originate from idiopathic, chromosomal, or metabolic abnormalities. Achondroplasia is one of the most common forms of skeletal dysplasia. It can affect the formation of the spinal canal and CSF drainage, and as a result, children with this condition are prone to the development of spinal stenosis, cervicomedullary compression, and hydrocephalus. Spinal stenosis is more frequently encountered as the patients age and can be addressed symptomatically with a decompression laminectomy. Given the high rates of progressive deformity, a fusion procedure is recommended for patients undergoing extensive laminectomies at the time of the decompressive procedure. Cervicomedullary decompression is a potentially life-saving procedure that^{54,55} removes pressure from the brainstem. Patients with achondroplasia in whom brainstem compression is a concern should undergo decompression in a timely manner because sudden death and developmental delays can result if the condition is left untreated. Hydrocephalus can also develop from skeletal stenosis of the CSF drainage pathways and jugular stenosis. Most patients with achondroplasia tolerate hydrocephalus well, but if there are concerns for increased ICP, a CSF diversion procedure should be considered.

Although the prevalence of achondroplasia in children in the population at large is relatively low, these children often have complex issues that require close monitoring and possible neurosurgical intervention. Other skeletal dysplasias also present with spinal instability or compression that can require neurosurgical intervention to address quality-of-life issues as well as significant medical concerns. Although there are inherent risks to any pediatric surgery, the potential benefit for these patients is significant.

Pearls

- Patients with achondroplasia should be managed by a multidisciplinary team. Regardless of the radiologic findings, surgery should not be offered unless the patient is symptomatic. However, careful neurologic follow-up is crucial, and surgery should be done at the first sign of neurologic compromise to avoid irreversible deficits.
- During cervicomedullary decompression, engorged veins lying below the ligamentum flavum both dorsally and laterally can be a source of significant bleeding.
- Dural tears can be commonly encountered during both cervicomedullary decompression and lumbar laminectomy. Urinary retention is commonly seen in the perioperative period and should be further investigated.
- Spinal fusion should be considered in pediatric patients with achondroplasia who are undergoing laminectomy, given the propensity of the vertebrae to develop deformity if left unfused.

31 Syringomyelia and Hydromyelia

Bermans J. Iskandar, Brandon G. Rocque, and Joshua E. Medow

Syringomyelia, or cystic cavitation of the spinal cord, is caused by various congenital, inflammatory, or traumatic problems of the brain and spine. Progressive syringomyelia causes neurologic deficits requiring surgical intervention. Although the cyst is often treated with direct drainage or shunting, treatment should ideally be directed at the etiology of the cyst. In this chapter, we review the incidence, pathophysiology, treatment options, and prognosis of syringomyelia as it relates to its various etiologies.

31.1 Definition

Spinal cord cavitation was first described in 1546 by Esteine in a treatise entitled *La Dissection du Corps Humain*.¹ The term *syringomyelia* was coined by D'Angers nearly 300 years later, in 1827.¹ In Greek mythology, Syrinx was “a nymph who was changed into a reed to save her from the amorous pursuit of Pan. From this reed, Pan then fashioned his musical pipes.”² Today, the term *syringomyelia* is used broadly to define a fluid-filled cavity (Greek *surinx*, “pipe”) within the parenchyma of the spinal cord (Greek *muelos*, “marrow”) that extends across more than one spinal segment. It is associated with a variety of pathologic conditions but is most frequently seen with hindbrain abnormalities such as the Chiari 1 malformation. It rarely causes death unless associated with bulbar symptoms.

Because syringomyelia comprises a family of disorders with different etiologies and potentially diverse pathophysiologic mechanisms, attempts have been made to classify it according to various criteria. Unfortunately, no classification scheme has satisfactorily illustrated all the major differences between the various forms of spinal cord cavitation. For instance, syringomyelia is divided into communicating and noncommunicating categories. A communicating syringomyelia consists of a cavity that communicates with the central canal and thus the fourth ventricle. Such a cavity is ordinarily surrounded by an ependymal lining and is located within the central canal, a condition also termed *hydromyelia* (► Fig. 31.1). In contrast, a syringomyelia is noncommunicating when the syrinx cavity does not involve the central canal. However, for the sake of simplicity in nomenclature, we use the term *syringomyelia* in all cases throughout this chapter.

31.2 Pathogenesis

The exact pathogenesis of syringomyelia is poorly understood. There is some evidence that in cases of direct compression of the spinal cord resulting from a mass, tight bony canal, tethering, or arachnoiditis, spinal cord edema may develop.^{3,4} Concomitantly, the patient may develop signs and symptoms of cord dysfunction that may return to normal or at least improve if the pathology is treated swiftly. Edema has been described as part of a “presyrinx” state and is well visualized on T2-weighted magnetic resonance (MR) imaging.^{3,4} When syringomyelia eventually develops, it can occur at any level, but it usually appears in close proximity to the area of known pathology and

extends from there. Nonetheless, most of the literature that attempts to dissect the pathophysiologic causes tends to argue a specific type of syringomyelia that results from hindbrain herniation. A discussion of these theories in detail is beyond the purpose of this chapter. Instead, readers are referred to the chapter on Chiari malformations and an excellent review of the subject,⁵ in which the hydrodynamic theory, the perivascular cerebrospinal fluid (CSF) dissection theory, the mechanical stress theory, and the intramedullary pulse pressure theory are described. Theories that relate more exclusively to other etiologies are discussed individually under the various etiologic subheadings.

31.3 Classification and Management of Syringomyelia Based on Etiology

31.3.1 Classification Scheme Based on Etiology

Conceptually, syringomyelia is a secondary abnormality caused by other spinal or cranial pathology. It is doubtful if primary syringomyelia actually exists, and it may be only a matter of time and improved technology before idiopathic syringomyelia can be explained and placed into previously undetected etiologic categories. One obvious example is that of the Chiari 0 abnormality, in which a pathophysiologic posterior fossa abnormality is assumed to be present (because the syrinx resolves with posterior fossa decompression) but which remains elusive anatomically (no posterior fossa abnormality is evident on diagnostic imaging). The anatomical problems currently recognized to cause syringomyelia include, but are not limited to, Chiari 1 and 2 malformations, congenital and acquired tethered spinal cord

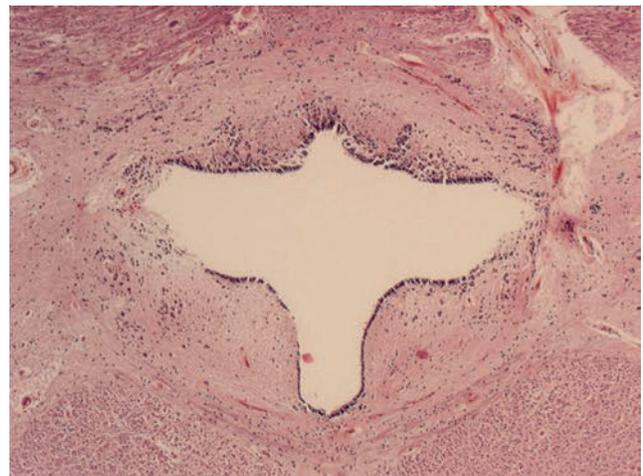

Fig. 31.1 Cross section of the cervical spinal cord showing a cystic cavity surrounded entirely by ependymal lining: “classic” hydromyelia.

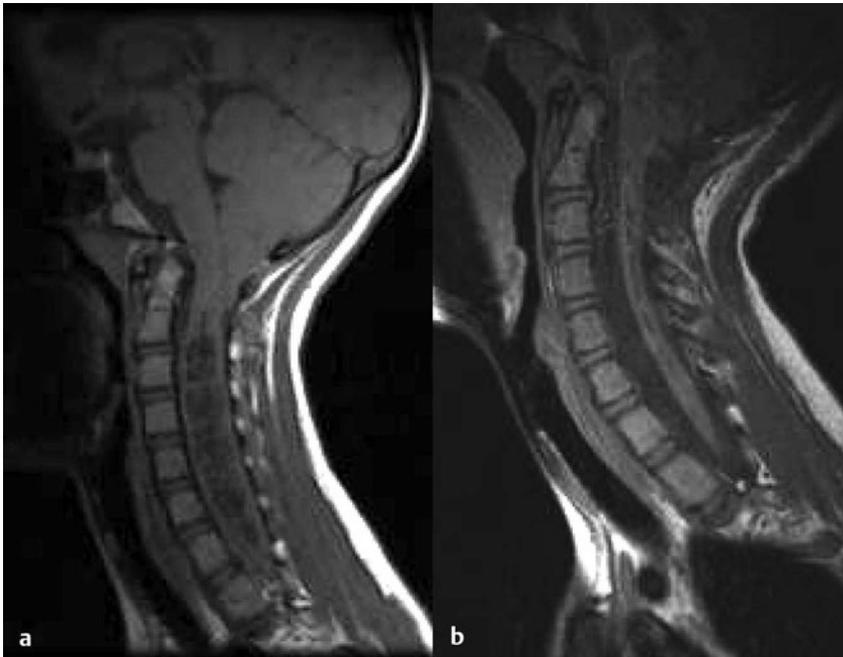

Fig. 31.2 (a) Sagittal magnetic resonance image of a 14-year-old girl with a Chiari 1 malformation and holocord syringomyelia. (b) Note the syrinx resolution after posterior fossa decompression.

(terminal syringomyelia), tumor, trauma, vascular malformation, degenerative stenosis and disk herniation, arachnoiditis, and infection. In this section, we classify syringomyelia based on these associated pathologies.

31.3.2 Management Scheme Based on Etiology

In general, the management of symptomatic syringomyelia is best approached by identifying and treating the associated condition thought to have caused the syrinx. The decision to treat syringomyelia surgically is straightforward when the patient is symptomatic, but treatment of the asymptomatic patient is more controversial. Small, asymptomatic syrinx cavities without any other obvious pathology may and often should be observed over time with serial imaging examinations. Conversely, an enlarging syrinx associated with progressive neurologic compromise merits timely surgical intervention. Difficulties arise in the large number of cases in which clinical or radiographic progression is not obvious, especially when no etiology is recognized (idiopathic syringomyelia) or when many potential etiologies coexist (e.g., spina bifida). Therefore, as with clinical presentation and pathophysiology, we discuss the general recommendations for surgical intervention according to etiology. The management algorithms presented after each section are guided by the literature but mainly reflect practice patterns garnered by the senior author's clinical experience.

31.3.3 Chiari 1

The Chiari 1 malformation consists of caudal displacement of the cerebellar tonsils into the upper cervical spinal canal approximately 5 mm below the plane of the foramen magnum. The vast majority of these malformations are congenital; however, acquired tonsillar herniation related to prolonged lumbar drainage or increased intracranial pressure has also been reported.

Although the occurrence of acquired hindbrain hernias only complicates the pathogenesis theories reported, it is reasonable to assume that syringomyelia in such cases is caused by a relative obstruction to the flow of CSF at the foramen magnum (► Fig. 31.2). Treatment almost uniformly consists of posterior fossa decompression. For data on the incidence, presentation, and treatment of syringomyelia associated with the Chiari 1 malformation, readers are referred to the relevant chapter in this textbook as well as the Chiari 1 Algorithm (► Fig. 31.3).

31.3.4 Chiari 2 (Spina Bifida)

The Chiari 2 malformation (or Arnold-Chiari malformation) occurs solely in patients with spina bifida and consists of caudal displacement of the cerebellar vermis, fourth ventricle, and brainstem.⁶ It is associated with hydrocephalus in more than 90% of patients and syringomyelia in 40 to 95%. The complicating factor in managing syringomyelia in patients with spina bifida is the fact that it is often difficult—if not impossible—to determine whether the syrinx is caused by hydrocephalus and shunt malfunction, Chiari 2, or a tethered spinal cord at the myelomeningocele repair site (► Fig. 31.4). However, it is increasingly apparent that regardless of the type of symptoms or imaging findings, the first treatment option to be considered should be cerebrospinal shunt revision (► Fig. 31.4). Readers are referred to the relevant chapter in this textbook and the Chiari 2 Algorithm (► Fig. 31.5 for more detailed information regarding this anomaly and its association with syringomyelia).

31.3.5 Chiari 0

Described in 1997, Chiari 0 defines idiopathic syringomyelia that improves in response to suboccipital decompression.⁷ Even though patients with Chiari 0 do not have tonsillar herniation on MR imaging, evidence suggests that Chiari 0 and Chiari 1 share clinical, radiographic, and genetic characteristics, as

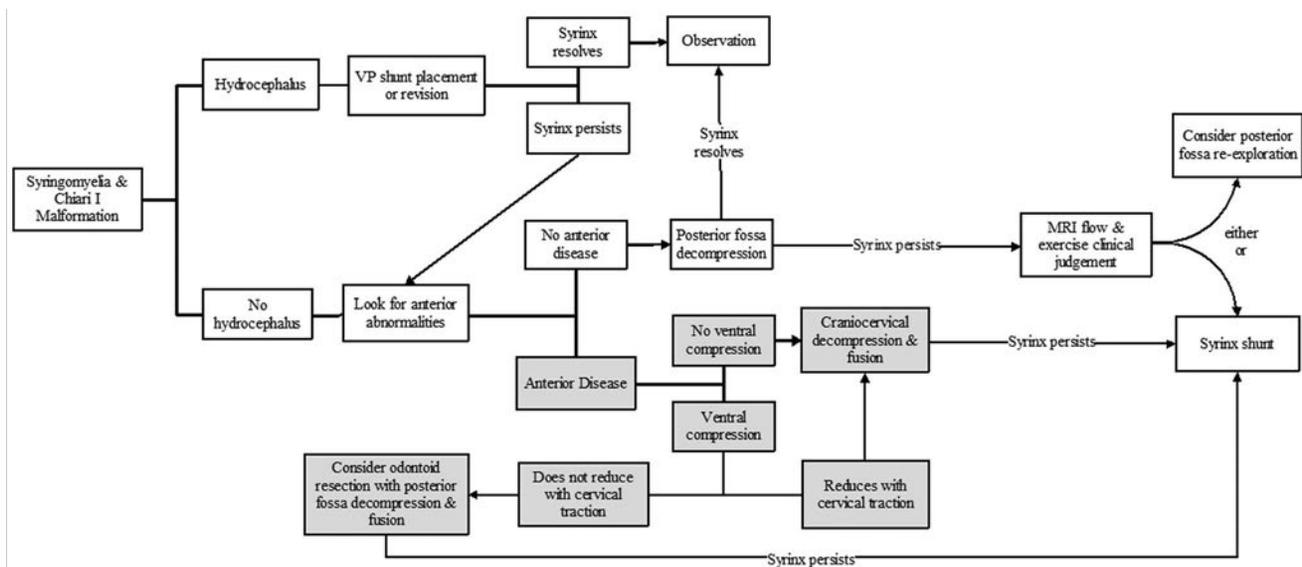

Fig. 31.3 Chiari I algorithm

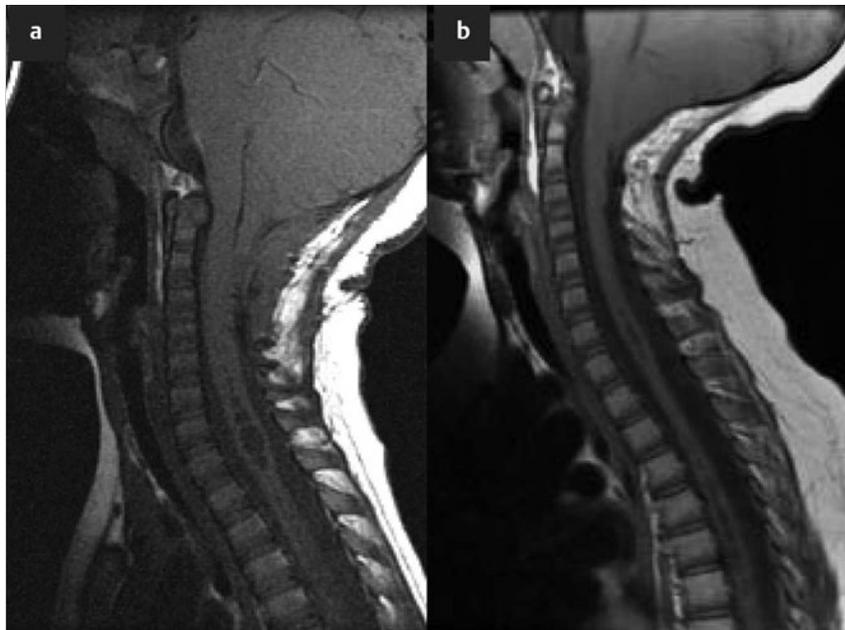

Fig. 31.4 (a) Sagittal magnetic resonance image of a patient with spina bifida showing a Chiari 2 malformation and syringomyelia. (b) The syrinx resolved after ventriculoperitoneal shunt revision.

detailed in the relevant chapter in this textbook.^{8,9} In general, however, the foramen magnum appears anatomically normal on imaging and intraoperative examination. This suggests that patients with Chiari 0 may have functional rather than anatomical obstructions at the foramen magnum,^{7,8,10} which one hopes can ultimately be identified with functional imaging modalities, such as cine flow MR imaging (see later section on imaging studies). It has further been hypothesized that Chiari 0 and Chiari 1 malformations are variants of the same disorder and have a common underlying pathophysiology. Regardless, our knowledge of Chiari 0 remains inadequate to determine the best treatment options (see Idiopathic and Chiari 0 Algorithm, ► Fig. 31.6). It is clear that some patients with idiopathic syringomyelia respond to posterior fossa decompression; 10 of 15

patients showed improved symptoms and signs after posterior fossa decompression in the largest series published to date.¹⁰ However, it is still unclear how these patients are different from other patients with idiopathic syringomyelia. Therefore, it is imperative to evaluate them thoroughly for other causative problems, such as tumors, arachnoiditis, and tethered cord, before any plan for posterior fossa decompression is made.

31.3.6 Tethered Cord (Terminal Syringomyelia)

Syringomyelia that occurs in the distal spinal cord, termed *terminal syringomyelia*, is often associated with spinal cord tethering. Tethered cord can be congenital or acquired. *Acquired*

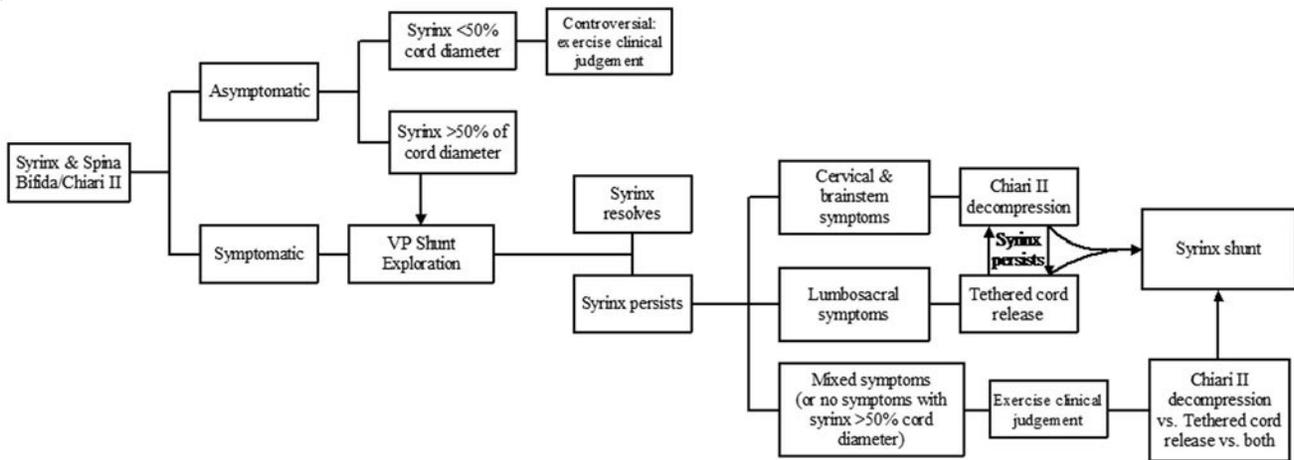

Fig. 31.5 Chiari II algorithm

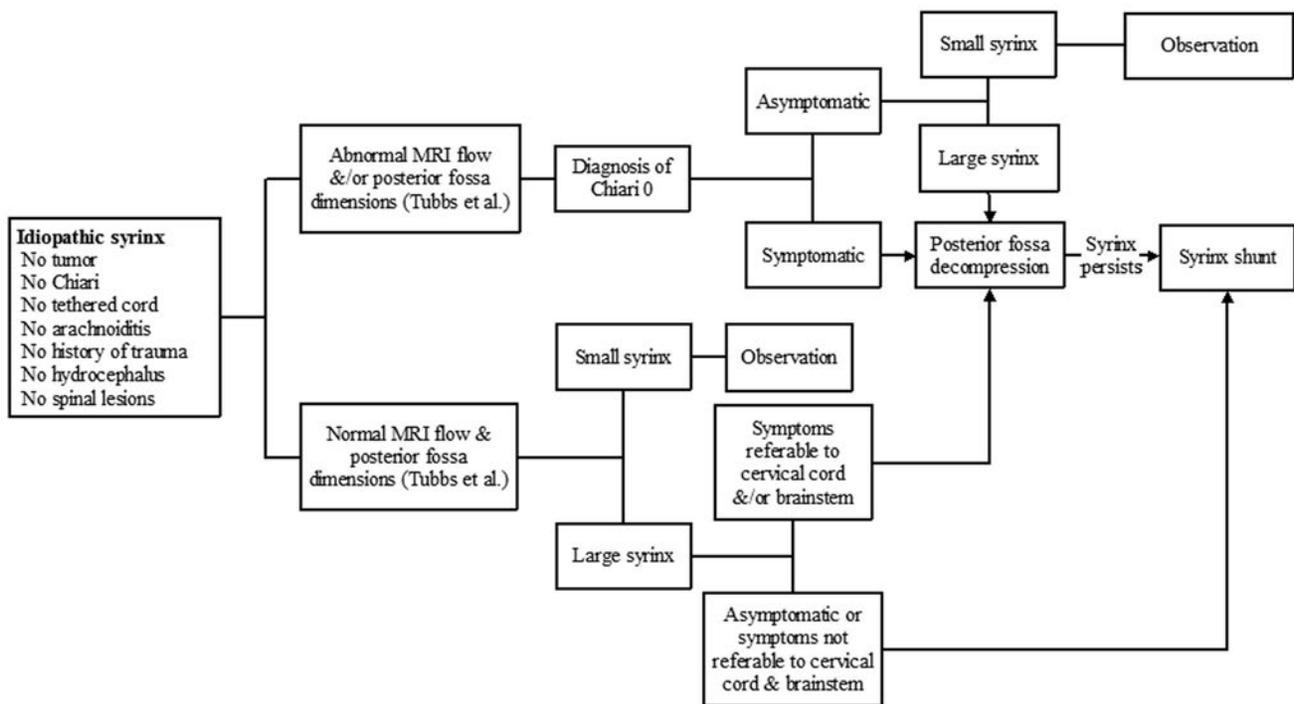

Fig. 31.6 Idiopathic and Chiari 0 algorithm

tethering usually occurs because of scarring, years after myelomeningocele repair. These patients are discussed in some detail in the earlier section on Chiari 2, and their cases are complicated by the fact that the Chiari 2 malformation and hydrocephalus may play a significant role in symptomatology and/or syrinx development. *Congenital tethered cord*, also known as spina bifida occulta, is associated with syringomyelia in 6 to 45% of cases (► Fig. 31.7). The spectrum of malformations that make up spina bifida occulta include tight filum terminale, split-cord malformation types 1 and 2, lipomyelomeningocele, dermal inclusion cyst with sinus tract, meningocele manqué, and neurenteric cyst.¹¹ Terminal syringomyelia associated with spina bifida occulta occurs in the distal third of the spinal cord¹²

(► Fig. 31.7). These patients do not have hydrocephalus, Chiari malformation, or other brain anomalies. The epicenter of the syrinx is usually located in close proximity to the tethering structure in the lumbosacral region. Patients with terminal syringomyelia often present with progressive bladder and lower extremity dysfunction. However, it is often impossible to distinguish between the symptoms associated with the syrinx and those associated with the cord tethering.¹² Releasing the tethered cord is essential in all patients with occult spinal dysraphism in order to prevent neurologic and urologic deficits, or the progression of already-existing deficits (see Congenital tethered cord algorithm ► Fig. 31.8).¹³ Older studies have suggested that when the associated syrinx is large in cross-section-

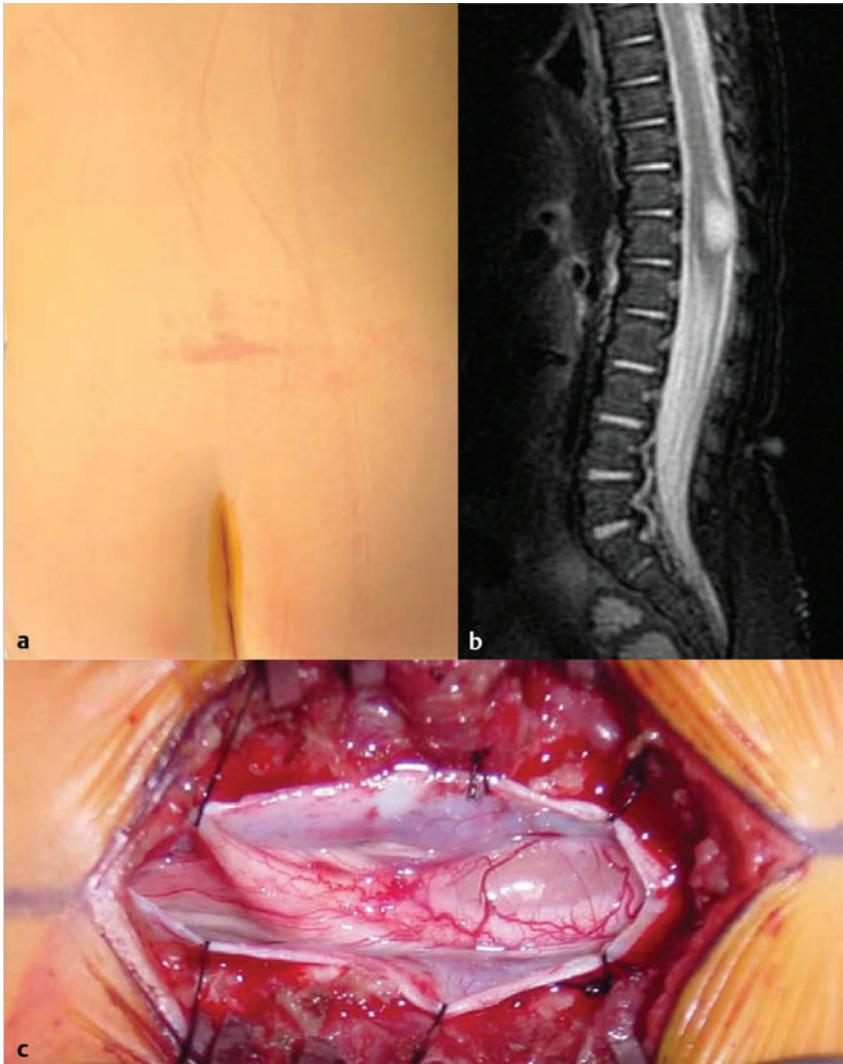

Fig. 31.7 (a) Terminal syrinx in a patient with a congenital tethered cord who presented with a lumbar hemangioma and (b) a conus in normal position. (c) Note the glistening surface of the thinned-out dorsal columns in the intraoperative photograph.

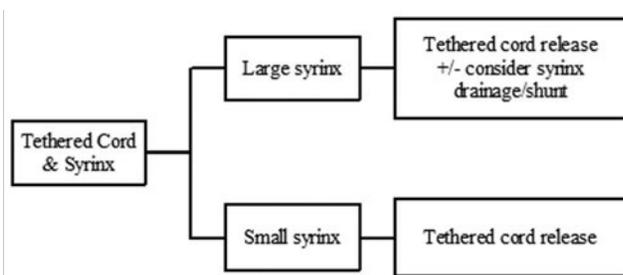

Fig. 31.8 Congenital tethered cord algorithm (terminal syringomyelia)

al diameter or extends for two or more vertebral levels in longitudinal dimension, it is preferable to place a shunt in addition to untethering.¹² However, more recent large studies have shown that terminal syringomyelia does indeed improve in response to untethering alone.^{14,15} Therefore, like syringomyelia due to foramen magnum pathology, syrinxes associated with tethered cord lesions appear to respond to correction of the underlying pathology, with a minority requiring direct shunting or drainage.

31.3.7 Arachnoiditis

Definition and Epidemiology

Spinal arachnoiditis can occur for a number of reasons, including infection (tuberculosis, bacterial or viral infection), chemical meningitis secondary to drugs and surgical interventions, and tumor (carcinomatous meningitis); even a familial form of spinal arachnoiditis has been described. Most commonly, however, it is associated with trauma. Imaging often reveals deformation of the spinal cord at the site of arachnoidal adhesions, blurring of a part of the syrinx wall (corresponding to the adhesive sites), flow void within the syrinx, and lack of abnormal contrast enhancement.¹⁶ In the series of Klekamp et al, the syrinx occurred above the level of arachnoiditis in approximately 40% of patients, below the level of arachnoiditis in 20 to 25%, and both above and below in 30 to 40%.¹⁷ Older studies had reported the relative success of syringoperitoneal shunting in treating patients with syringomyelia secondary to adhesive arachnoiditis.¹⁸ Since then, it has become obvious that most syrinx shunts are likely to fail, and once they fail, revisions are fraught with complications.^{17,19} Subsequently, the more recent literature has reported improvement in outcomes when shunting procedures

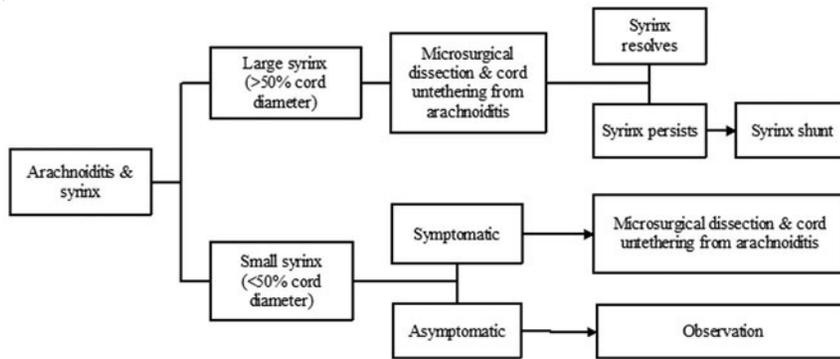

Fig. 31.9 Arachnoiditis algorithm

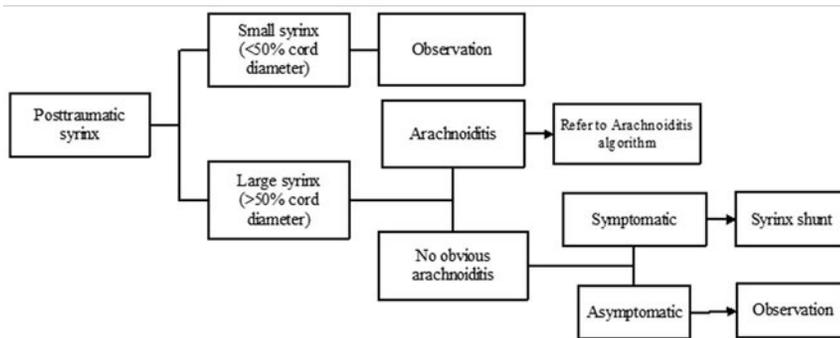

Fig. 31.10 Trauma algorithm

were abandoned in favor of microsurgical dissection and untethering of the cord.^{19,20} In such cases, it is hypothesized that decompressing the part of the spinal cord that is tethered by the arachnoiditis leads to the re-establishment of subarachnoid patency and physiologic CSF flow.^{17,21,22} Regardless of the treatment modality, however, these patients continue to experience unpredictable rates of syrinx recurrence (see Arachnoiditis algorithm, ► Fig. 31.9).^{17, 22}

31.3.8 Trauma

Although uncommon, syringomyelia is a well-known sequela of spinal cord trauma.^{23,24} Syringomyelia secondary to trauma is of clinical importance because of both the potential for progressive neurologic deterioration and the opportunity for successful surgical management when it is diagnosed. The exact incidence of symptomatic syringomyelia after trauma is unknown but is estimated to be 2 to 5%; however, the incidence of symptomatic syringomyelia in patients with spinal cord injury has been reported to exceed 50% in some series.^{25,26} Additionally, the clinical picture of this condition is often complicated by the extreme temporal variability in the initial presentation of the syringomyelia, ranging between 2 months and 36 years after the initial injury.^{27,28} Posttraumatic syringomyelia can be caused by arachnoiditis, as described in the previous section; alternatively, spinal cord contusion or infarction with hematoma may evolve into necrosis and cavitation.³² Although most small posttraumatic syrinxes remain stable, focal arachnoiditis can cause further injury to the spinal cord, perpetuating syrinx evolution. Regardless of the mechanism, once the initial cyst forms, subsequent events must take place that result in further enlargement and development of the syrinx. Perhaps surprising is the

documentation that most patients seeking medical attention for posttraumatic syringomyelia report relatively minor trauma. Despite these epidemiologic data, studies of posttraumatic syringomyelia most often involve patients with either complete or incomplete spinal cord injury who have been rendered paraplegic or quadriplegic as a result. Bonfield et al³³ identified 22 studies that met inclusion criteria and determined that all of the studies had evidence of poor or very poor quality, with no randomized controlled trials or multicenter series. Despite the poor quality of the evidence, these investigators were able to conclude that patients with complete spinal cord injury have a higher risk for syringomyelia than those with incomplete injury. Pain is by far the most commonly reported presenting symptom in this group of patients with syringomyelia.^{17,34,35} Additionally, patients have reported sensory loss, paresthesias, progressive weakness, and less commonly ataxia, spasticity, sphincter disturbance, swallowing dysfunction, and autonomic dysfunction. It should also be noted that in numerous studies, the severity of symptoms did not correlate with the size of the syrinx cavity.^{36,37}

Treatment of an Enlarging Syrinx or Progressive Symptoms

When there is progression of neurologic deficits, surgical treatment of the syrinx may become important (see Trauma algorithm, ► Fig. 31.10). However, spinal cord trauma often causes progressive cord atrophy leading to neurologic deterioration that does not respond to any surgical intervention.⁴⁰ Therefore, before the patient is committed to a surgical procedure, careful review of the MR images should differentiate between a syrinx that expands the spinal cord versus an ex vacuo cyst with

associated cord atrophy.^{38,39,40} Furthermore, although it is well established that a progressively enlarging syrinx should be treated surgically, controversy remains regarding the most effective type of treatment. Few authors recommend draining the syrinx with a stent or shunt, with the distal end of the shunt placed in the subarachnoid space, pleura, or peritoneum. Although early reports of these techniques showed encouraging results, long-term outcomes have been disappointing at best, with an 80 to 100% syrinx recurrence rate in one series.¹⁷ Based on a systematic review of the literature, the preferred surgical technique for posttraumatic syringomyelia is spinal cord untethering with expansile duraplasty, although it must be reiterated that this recommendation is based on case series only.³³

Treatment of a Stable Syrinx with Associated Pain

Posttraumatic syringomyelia is occasionally related to ex vacuo cavitation from a hemorrhagic contusion rather than from cystic expansion secondary to obstruction, and the pain

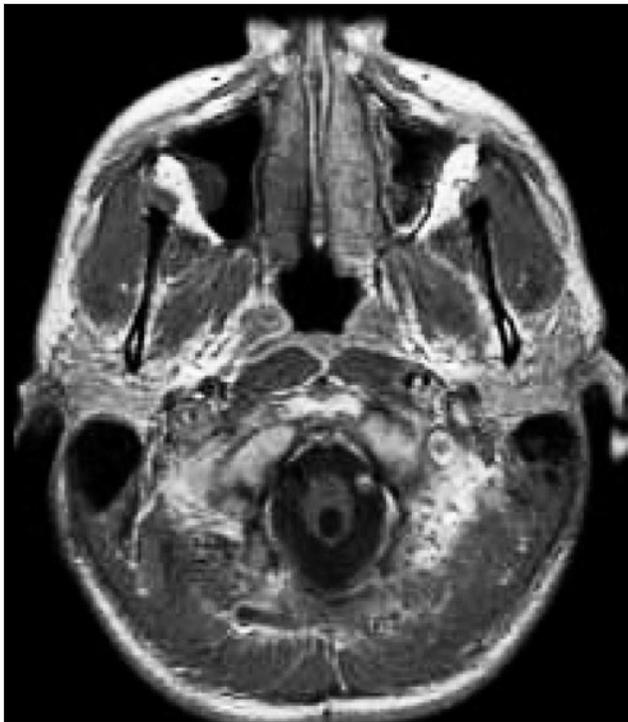

Fig. 31.11 Syringobulbia secondary to a cervicomedullary hemangioblastoma. The cyst decreased significantly in size within a year of tumor resection.

associated with such syringomyelia does not ordinarily respond to surgical treatment of the syrinx. In these cases, other methods of treatment for the pain have been attempted, including spinal cord stimulation, intrathecal morphine pump, thalamotomy, dorsal root entry zone (DREZ) procedures, and others, all of which have shown variable but usually poor results. Outcome reporting in the population with trauma is difficult because the end points of success and failure are not well demarcated. In addition, survival in this group is often decreased, preventing adequate long-term follow-up and assessment.

31.3.9 Tumors

Tumors pose an interesting diagnostic dilemma in patients who have a cyst within the spinal cord parenchyma. Of course, syringomyelia can be associated with posterior fossa tumors,^{41,42} as well as spinal tumors that are extradural; in such cases, the syrinx almost always responds to treatment that is directed primarily at the tumor. However, our interest in this chapter is to present the association between syringomyelia and tumors arising in the spinal cord proper. These cystic structures can be seen in 25 to 60% of all patients with intrinsic spinal cord tumors (refer to the chapters on spinal cord tumors.^{43,44,45,46} The tumor types most likely to cause syringomyelia are ependymomas and hemangioblastomas (► Fig. 31.11) and, less frequently, astrocytomas of any grade. Syringes associated with spinal tumors can be classified into two main types: cysts caused by an obstructive phenomenon that interrupts CSF flow, akin to syringes with other etiologies; and tumor cysts caused by the secretion of fluid by tumor cells, similar to the cysts that accompany intracranial gliomas. Whereas obstructive syringes contain fluid identical to CSF, true tumor cysts contain fluid with a high protein concentration. Certainly, as in the brain, true syringes and proteinaceous cystic cavities should be distinguished from tumor necrosis. A necrotic cavity, by definition, carries a worse outcome because it may denote a higher-grade tumor; in addition, such a cavity is ordinarily lined with tumor cells, which may influence the type and extent of resection needed. The main treatment option in patients with tumor-associated cysts is tumor resection, with little need for direct syrinx drainage (see relevant chapters in this textbook and Tumor algorithm, ► Fig. 31.12). In their review of 44 patients who had von Hippel-Lindau disease with spinal hemangioblastomas, Lonser et al⁴⁵ showed that the syrinx resolved in all patients after tumor removal, regardless of whether or not the syrinx cavity was entered.

31.3.10 Other Spinal Abnormalities

A number of other anatomical findings have been associated with syringomyelia, including spinal stenosis, herniated nucleus

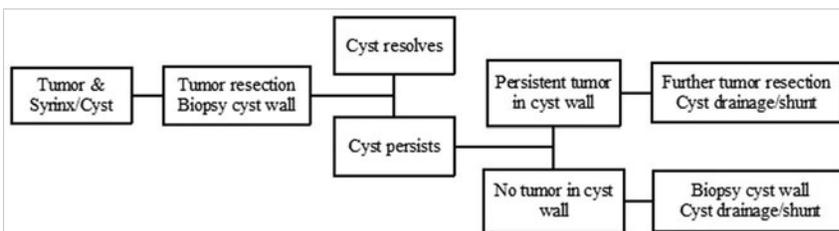

Fig. 31.12 Tumor algorithm

Fig. 31.13 Small syrinx associated with a disk herniation in a patient with radiculopathy and sensory loss over the shoulder and upper arm. This case exemplifies the difficulty in determining a cause-and-effect relationship between the cyst and the spondylosis, especially when the symptoms are poorly localizing.

pulposus (► Fig. 31.13), spinal subluxation, vascular malformations, and severe kyphoscoliosis. Patients with congenital problems such as achondroplasia (► Fig. 31.14), osteogenesis imperfecta, mucopolysaccharidosis, and others are likely to have spinal deformities such as craniocervical compression and spinal stenosis, some of which are associated with syringomyelia. Although treating the inciting etiology (e.g., disk herniation) is often sufficient to bring on resolution of the cystic cavity, it is important to ensure that the two lesions are related, not coincidental (see Other spinal anomalies algorithm, ► Fig. 31.15).⁴⁷ For instance, it is not unusual to encounter a small syrinx in association with an incidental disk bulge. The readers are cautioned about prematurely assuming a cause-and-effect relationship between the two pathologies.

31.3.11 Idiopathic Syringomyelia

Idiopathic syringomyelia is a diagnosis of exclusion made when no other treatable pathology can be identified. This category most likely represents a collection of abnormalities with varied etiologies that are difficult to discern. The best example is that of the Chiari 0 malformation, in which idiopathic syringomyelia is presumably relieved by posterior fossa decompression. This may indicate that the foramen magnum is abnormal, although such abnormalities are not evident on imaging studies. It is reasonable to think that with the availability of more accurate diagnostic measures (better flow studies, MR imaging sequences that can demonstrate subtle arachnoiditis, or even MR imaging spectroscopic techniques that may show evidence of trauma to the cord not visible on standard imaging), some of the diagnostic problems seen with idiopathic syringomyelia will be resolved. Most idiopathic syrinx cavities are small and discovered on MR imaging performed to investigate possible causes of scoliosis or pain (► Fig. 31.16).^{48,49,50} They may represent a large central canal and consequently seldom progress. However, some syrinxes are large and progressive, necessitating surgical treatment. The treatment of idiopathic syringomyelia should be guided by the cyst's anatomical characteristics and the patient's clinical status. Important characteristics include size (length

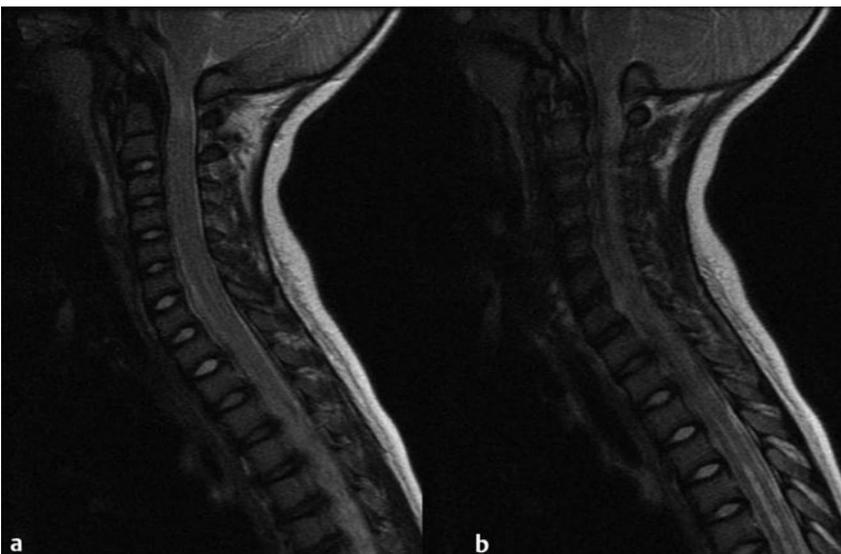

Fig. 31.14 (a) Infant with achondroplasia who presented with craniocervical stenosis and upper cervical signal abnormality on T2-weighted images, indicating cord compromise at that level. (b) Note the associated syringomyelia in the low cervical and upper thoracic region.

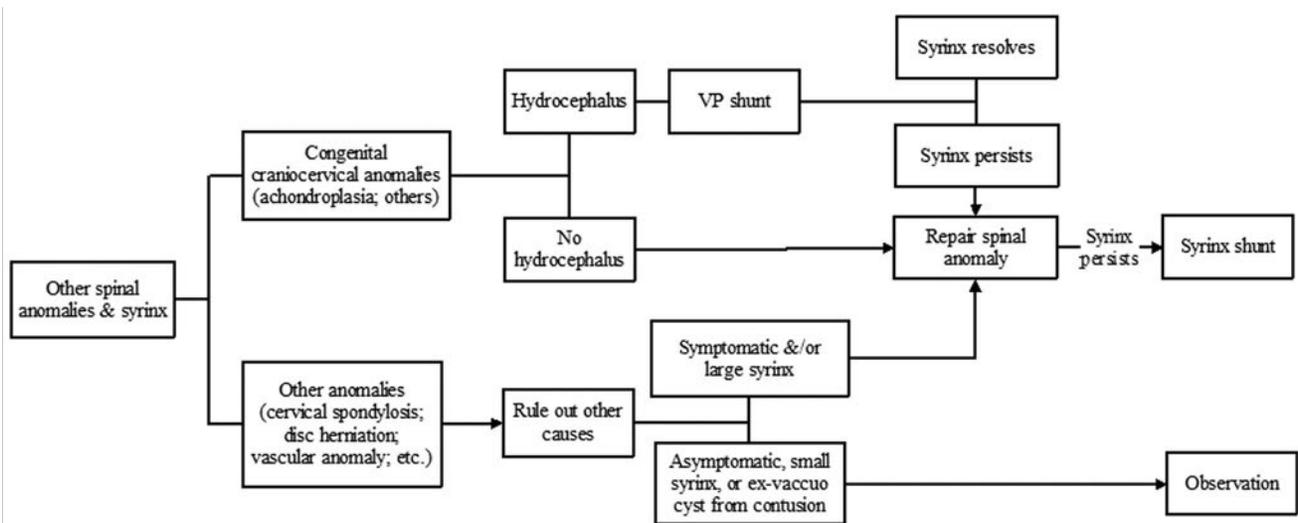

Fig. 31.15 Other spinal anomalies algorithm

Fig. 31.16 Idiopathic “thin” syrinx, likely representing an enlarged central canal and not requiring treatment.

and width), whether the spinal cord is enlarged or thinned out by the cyst (ratio of cyst diameter to cord diameter), and whether it is atrophic. It is crucial to ascertain whether the cyst is an ex vacuo result of a spinal cord injury, inflammation, infection, or vascular event, as opposed to the result of a disturbance in CSF flow leading to a buildup of pressure within the spinal canal, which would be caused by arachnoiditis, veils, or infection. The symptomatic state of the patient may also determine treatment. Ex vacuo cysts may be associated with symptoms such as central pain and dysesthesias and may even be associated with a stable motor or sensory deficit caused by the inciting event (infection, stroke, unrecognized trauma). Ordinarily, such cysts are not drained. Instead, treatment is directed at the symptoms (i.e., pain) with the use of various drugs or even surgical augmentative procedures (e.g., spinal cord stimulation) or ablative interventions (e.g., thoracic DREZ,⁵¹ thalamotomy).

Thin idiopathic syrinxes are usually asymptomatic. They are often indistinguishable from a large central canal (a normal variant^{48,52} that may occupy a significant length of the spinal cord) or a ventriculus terminalis⁵³ (a small cystic structure located at the tip of the conus medullaris, often extending into the filum terminale and representing an embryologic remnant of the terminal ventricle). In a multi-institution review of 48 patients with idiopathic syrinxes, 32 of whom had clinical and radiographic follow-up with a mean of 24 months, 28 of 32 had stable or improved symptoms, and 28 of 32 had stable or decreased syrinx size.⁵⁰ Based on this report, it may be concluded that most idiopathic syrinxes are unlikely to worsen. However, a syrinx can be labeled idiopathic only after a thorough investigation to detect possible underlying causes, including the following: subtle spinal cord tumors, arachnoiditis, arteriovenous fistulas, disturbance of the foramen magnum CSF flow, subtle anatomical abnormalities at the foramen magnum that could lead to the diagnosis of Chiari 0,^{7,8} and a tethered spinal cord from a tight filum terminale with a normally positioned conus medullaris.⁵⁴ ⁵⁵ If no cause can be identified and the syrinx is enlarging or the symptoms are worsening, there are several options for

treatment (see Idiopathic and Chiari 0 algorithm, ► Fig. 31.6): (1) direct shunting of the syrinx (syringo-subarachnoid, syringopleural, or syringo-peritoneal shunt); (2) posterior fossa decompression; (3) tethered cord release; and (4) observation and serial imaging. Such decisions can be very difficult and are usually made on a case-by-case basis depending on the clinical presentation.

31.4 Clinical Syndromes

The clinical presentation of patients with syringomyelia is diverse and depends on two main factors: the anatomy of the cyst cavity (location and size) and the etiology of the syrinx. For this reason, we have described the different clinical presentations under various etiologic subheadings. The readers are referred to the literature for discussions of the more typical neurologic syndromes seen with syringomyelia, including dissociated sensory loss, central cord syndrome, and brainstem signs, and the less typical Lhermitte phenomenon,¹ hand deformities,⁵⁶ neurogenic arthropathies (Charcot joints),^{57,58} and hyperhidrosis.^{1,59} However, a short discussion of scoliosis and pain is relevant.

31.4.1 Scoliosis

Scoliosis that occurs in association with syringomyelia is assumed to have resulted from lateralized anterior horn compression, creating an inequality of paravertebral muscle strength, with subsequent collapse of the vertebral canal.⁶⁰ In patients who present for a work-up of scoliosis, young age at presentation, atypical curve, rapid curve progression, and back pain have been found to correlate with associated syringomyelia.⁶¹

Treatment of the Syrinx

When associated with other clinical manifestations, there is little doubt that the syrinx or its etiology should be treated because treatment has shown better results in comparison to bracing or observation.^{60,62,63} However, there is some controversy as to whether syrinx treatment is indicated in the setting of scoliosis without other symptomatology and without radiographic progression of the cyst cavity. The advantage of early treatment is that if the scoliosis curvature is mild to moderate,^{60,62,63,64} the likelihood that the syrinx will stabilize without the need for fusion is high. This has also been demonstrated in scoliosis of other causes. For instance, Pierz et al showed that tethered cord release in patients with spina bifida improves curves that measure less than 20 degrees, whereas fusion is eventually required for most curves that exceed 30 degrees.⁶⁵ Furthermore, surgical management of scoliosis with an unrecognized syrinx is reported to increase neurological complications.⁶²

Treatment of the Scoliosis

Depending on the patient's age and rate of progression of the spinal curvature, corrective surgery (spinal fusion) may be necessary. The goal is to prevent progression, relieve medically intractable pain, and prevent incapacitating deformities. However, scoliosis surgery is associated with considerable risk for blood loss and neurologic injury; therefore, such a decision

requires extensive planning and a multidisciplinary approach. In some situations, bracing can be considered as a temporizing measure until the child is older or until there is evidence of progression of the curvature. Finally, it is important to reaffirm that when syringomyelia is the cause of the scoliosis, the syrinx should be treated first.⁶²

31.4.2 Pain

Spinal cysts, especially those associated with severe spinal cord trauma, can present with pain perceived to be of central origin (i.e., arising in the injured spinal cord).⁵¹ Specifically, two different pain syndromes develop in patients after spinal cord injury: (1) segmental or radicular “dull and aching” pain occurring just below the level of the injury, often in the transitional zone, which is thought to result from direct injury to the nerve roots or arachnoiditis;(2) diffuse, burning pain occurring below the level of injury and involving the entire body below or remote regions (“phantom limb” pain).⁶⁶ Because syringomyelia is associated with pain in the majority of these patients, it is virtually impossible to separate the symptoms related to the initial spinal cord damage from those related to the cyst. In fact, shunt placement in the cyst rarely results in diminution of the pain. Therefore, unless the cyst is large or enlarging, it is not usually treated surgically. Instead, treatment is directed at the symptoms with the use of various drugs or even surgical interventions such as spinal cord stimulation, DREZ, thalamotomy, and others.

31.5 Diagnostic Imaging

31.5.1 Static Magnetic Resonance Imaging

Most of the diagnostic issues related to syringomyelia rely exclusively on MR imaging. An uncomplicated syrinx is filled with fluid that is isointense to CSF on T1- and T2-weighted sequences.⁶⁷ High concentrations of fluid in the cord adjacent to the syrinx may represent gliosis.⁴³ The walls of the syrinx cavity are often irregular, especially as the syrinx enlarges. Periodic folds, septa, or haustra are visible. The inner aspect of the cavity may appear to be septated owing to collagen bands or hyalinized blood vessels traversing the syrinx. These septa are often incomplete, allowing the syrinx fluid to communicate throughout the cavity. Syrinx cavities are not expected to enhance. Thus, if tumor is suspected, gadolinium-enhanced T1 MR images should be obtained. If the cyst enhances, it is not likely to be a true syrinx, and further evaluation for a tumor should be performed. The search for the etiology of a syrinx through imaging requires the use of enhanced MR imaging to rule out tumor and arachnoiditis, as well as full posterior fossa and spinal MR imaging to rule out Chiari malformations and tethered cord.

31.5.2 Cine Magnetic Resonance Imaging

Phase-contrast MR imaging has been used to analyze the flow of CSF through the foramen magnum in patients with Chiari 1 malformation. Some investigators have used this MR technique to report increased pulsatility of the cerebellar tonsils and

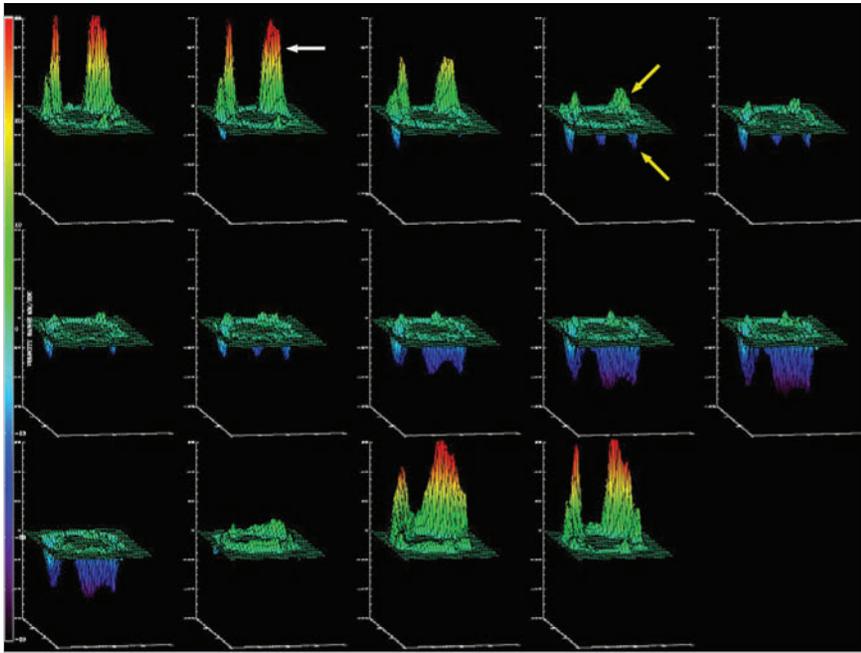

Fig. 31.17 Detailed analysis of cerebrospinal fluid flow velocities at the foramen magnum of a child with a Chiari 1 malformation. The flow velocity in each voxel is computed; all velocities are then color-coded and plotted in consecutive images representing 14 time points of the cardiac cycle. Note that there is a predominance of cephalad flow in seven of the images, and caudad flow in the other seven images. This color plot of velocities displays the cephalad velocities in green, yellow, and red, with green slowest and red fastest; caudad flow is displayed with light blue, deep blue, and violet/black, with light blue slowest and violet/black fastest. Children with symptomatic Chiari 1 show jets (*white arrow*) of elevated velocities in the anterior quadrants of the foramen magnum (red color for velocities nearing 10 cm/s). The extreme caudad velocities are not well appreciated in the surface plots because of the dark background. Finally, note the bidirectional flow (*yellow arrows*), indicating that cephalad and caudad velocities coexist at one time point. Such regional jets and bidirectionality of flow are not present in normal individuals.

spinal cord in patients with Chiari 1 malformation, suggesting that these motions may contribute to the velocity of CSF flow. In addition, phase-contrast techniques have been used to measure CSF velocities, but with no significant improvement in our understanding of the pathophysiology of these lesions.^{68,69} Phase-contrast MR imaging has been used successfully to calculate both bulk flow and average CSF velocities at the foramen magnum. Although these studies have provided data regarding the relative general obstruction of flow within the foramen magnum, and have certainly been helpful in evaluating patients with severe flow obstruction, they have failed to show a consistent difference between normal subjects and those with Chiari 1 that is mild or not yet symptomatic. In 1994, Armonda et al suggested that there is spatial heterogeneity in CSF velocity at the foramen magnum, which seems to correlate with symptoms.⁷⁰ However, to date these techniques have been largely unable to determine which patients are likely to benefit from surgical intervention.⁷¹ According to the Monro-Kellie doctrine, CSF flow through the foramen magnum is dictated by the intracranial systolic pressure wave. The volume of CSF moving in and out of the cranial vault through the craniocervical junction is therefore not affected by the size of the foramen magnum. Instead, any process that restricts flow within a portion of the foramen magnum is more likely to increase the velocity of flow than to decrease the volume of flow. When fluid moves at a constant rate through a progressively diminishing lumen, the pressure differential across the narrowed lumen progressively increases, causing fluid to move with greater velocity. Similarly, when fluid moves intermittently through a narrowed foramen magnum, the pressure differential across the foramen magnum is increased. Hypothetically, tonsillar herniation, adhesions within the foramen magnum, and other processes that narrow the foramen magnum increase the average bulk flow and velocity through that region. Under anatomically homogeneous circumstances, such a theory can be successfully applied to the Chiari 1 malformation. However, because of the anatomical

variability related to the tonsillar herniation, such pathophysiologic explanation does not suffice. In their preliminary studies, Haughton et al built upon the information collected from previous studies of CSF velocity and bulk flow in an effort to study the extent to which such flow is spatially or temporally heterogeneous. Specifically, they found significant elevation of CSF systolic or diastolic peak velocities in specific regions within the foramen magnum, but not in others⁷² (► Fig. 31.17). Moreover, they showed that these abnormally high peak systolic CSF velocities in patients with Chiari 1 exceed those in normal subjects and improve postoperatively.^{72,73} Follow-up studies revealed nonzero net flow and bidirectional flow within specific voxels in the foramen magnum, indicating that the overall flow is truly disturbed in both adults and children.^{74,75} By expanding on the various temporal and spatial indices of heterogeneity identified, it eventually may be possible to develop a comprehensive and organized understanding of foramen magnum fluid physiology, with emphasis on particular flow signatures corresponding to specific clinical scenarios. This is obviously contingent on further improvement in MR imaging and bioinformatics. The eventual goal is to understand the pathophysiology of syringomyelia and the Chiari 1 malformation in children and adults, and potentially to anticipate the onset of neurologic symptoms and signs to allow early intervention.

31.5.3 Computational Models of Syringomyelia

In recent years, researchers in biomechanical engineering and physics have taken up the challenge of studying syringomyelia and posterior fossa pathology. These groups have applied the principles of computational fluid dynamics to Chiari and syringomyelia pathologies, using hydrodynamic modeling to characterize the region of interest (i.e., the foramen magnum) and predict the interactions of its components. Computation fluid

dynamics derives its models from anatomical and flow data obtained with static and cine MR imaging. The goal is to provide both spatial and temporal models of CSF flow that can be individualized to a patient's specific parameters, and thus improve treatment and surgical planning for these conditions. For example, an early study was conducted to determine the properties of a healthy spinal canal.⁷⁶ A more recent study has shown CSF movement in the perivascular spaces of the spinal cord that is due to differences in the timing of CSF and arterial pulsations,⁷⁷ potentially lending credence to theories of syrinx pathogenesis that involve perivascular fluid movement.

31.6 Surgical Approaches

The impact of surgical treatment on the natural history of patients with Chiari malformations and syringomyelia has not been explored with randomized prospective studies. Such an undertaking would be difficult because of the perceived benefits of surgery, which include an observable improvement in symptoms and radiographic findings. Considerations that are generally agreed upon include rectifying hydrocephalus before any other corrective surgery is undertaken, and approaching the pathologic cause of the syrinx rather than the syrinx itself whenever possible. Most of the indications and algorithms are presented in the section on classification based on etiology. Surgical techniques for the Chiari malformations, tethered cord, and other etiologies are described in detail elsewhere in this textbook. Here, we briefly describe the surgical techniques used to directly drain or shunt a syrinx.

The use of syrinx-to-subarachnoid shunts is controversial. Some surgeons have used them to replace decompressive procedures,^{78,79,80} whereas others have used them concomitantly with surgery for the causative problem, such as suboccipital decompression for a Chiari 1 malformation. Current recommendations, however, suggest treating the pathology associated with the syrinx first, if at all possible. When the syrinx is not amenable to treatment in that fashion, syrinx shunting should be considered. Syrinx shunting may also be considered in patients with severe arachnoiditis who are likely to fail lysis of adhesions (see Recurrent syrinx algorithm, ► Fig. 31.18). This is advocated as a primary therapy in cases of posttrau-

matic syringomyelia with no obvious associated arachnoiditis and with a low level of suspicion for a foramen magnum CSF flow problem. Shunting is not limited to the subarachnoid space; shunts can be placed in the pleural space and peritoneal space as well. This procedure may be effective if shunting to the subarachnoid space is complicated by severe arachnoiditis or other anatomical problems within the spinal canal.

31.7 Conclusion

The diagnosis and treatment of syringomyelia can significantly impact the progression of symptoms and may improve neurologic outcomes regardless of the duration of the pathology. However, patients who have not had long-standing symptoms fare better than those with debilitating deficits. The advent of MR imaging has improved the timely diagnosis of syringomyelia before significant neurologic progression. Treatment varies with the type of pathology present. Because no single theory has been able to explain the pathogenesis of syringomyelia, a clear approach to treatment continues to evade physicians. A combination of clinical judgment, anecdotal reports, and case series data is used to provide patients with conservative or surgical options. Restoration of normal CSF flow is the goal of most operative interventions. Thus, in many cases, it is advised that the underlying pathology be treated rather than the syrinx directly. We suggest that syrinx shunting should be reserved for patients who do not respond to first-line surgery. In fact, some surgeons consider that a failed first-line therapy should be repeated or improved upon before a syrinx is drained directly. Moreover, idiopathic syringomyelia may well represent a collection of disorders with origins that are yet unidentifiable with current diagnostic techniques. Chiari 0, or posterior fossa abnormalities without obvious MR imaging correlates, which responds to craniocervical decompression, probably explains a subset of those cases. It is likely that other currently unknown origins exist as well. Finally, it is important to recognize the impact of hydrocephalus. Hydrocephalus should be diagnosed and treated before any other surgical procedure is undertaken. With astute clinical acumen, knowledge of anatomy, and an understanding of the conditions associated with syringomyelia, physicians will continue to alleviate symptoms and advance the study of this disease.

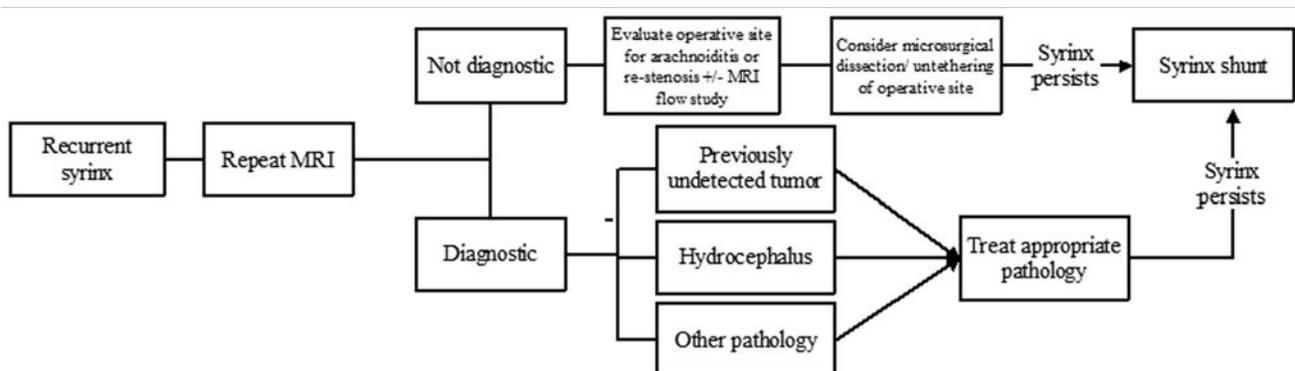

Fig. 31.18 Recurrent syrinx

Pearls

- Syringomyelia is a cystic cavitation of the spinal cord caused by different cranial and spinal abnormalities, such as Chiari malformation, tumor, and trauma.
- The pathophysiology of syringomyelia remains misunderstood, but the use of evolving MR imaging technology may help elaborate such a mechanism of pathogenesis.
- The fundamental goal in the diagnosis of syringomyelia is to identify the etiology of the cyst.
- The management of symptomatic syringomyelia is best approached by treating the associated condition thought to have caused the syrinx, thus re-establishing CSF flow and subarachnoid patency. Direct syrinx shunting should be used only as a last resource.
- A small and asymptomatic syrinx will often not require treatment.
- Chiari 1-related syringomyelia is best treated with posterior fossa decompression.
- Chiari 2-related syringomyelia should be assumed related to CSF shunt malfunction until it is proven otherwise, regardless of brain imaging findings.
- Syringomyelia may recur many years after the initial treatment. Thus, patients with a syrinx should be followed on a long-term basis, both clinically and radiographically.

32 Scalp and Skull Neoplasms

Dale M. Swift and David J. Sacco

Children are frequently evaluated by neurosurgeons and other medical professionals for bumps on the head, but in reality neoplasms of the scalp and skull are relatively rare. In the pediatric population, tumors in this location comprise a diverse array of pathologies quite different from those seen in adults. Pediatricians, dermatologists, plastic surgeons, general surgeons, and otolaryngologists, as well as neurosurgeons, commonly evaluate children with scalp or skull masses. Therefore, clinical experience with these relatively rare lesions is limited in any given practice. The published medical literature reflects this, consisting mostly of case reports, which tend to concentrate on atypical presentations and small case series that are limited by patient preselection.¹ Standardized protocols for the evaluation and treatment of children with scalp and skull tumors are lacking.²

Pediatric neurosurgeons are uniquely equipped to treat masses of the scalp and skull. Experience gained with modern techniques of craniofacial surgery charges the surgeon to consider the aesthetics of reconstruction as well as the efficacy of resection in the treatment of these lesions. Knowledge of the natural histories of specific neoplasms of this region, as well as familiarity with current adjuvant treatment regimens, will assist the neurosurgeon in planning both the resective and the reconstructive procedures.

32.1 Differential Diagnosis

The majority of “lumps on the head” called to medical attention are not neoplastic. Congenital, posttraumatic, and inflammatory lesions frequently present as masses of the calvaria. An extremely wide range of pathologies appears in this location. General reviews of surgically treated scalp and skull masses in children show that about one-half are dermoid cysts.^{3–6} The remaining diagnoses consist of a wide variety of dissimilar lesions (► Table 32.1).

The diagnosis is often obvious on physical examination; at other times, radiographic or histologic examination is necessary. Patients referred for evaluation of a scalp “lesion” or “mass” sometimes have an atypical form of an otherwise easily recognizable diagnosis, such as a meningoencephalocele. Congenital lesions are discussed in other chapters of this book and are included here for completeness only. Entities such as Langerhans cell histiocytosis, aneurysmal bone cyst, and fibrous dysplasia may not be truly neoplastic, but they share presentation and treatment patterns with neoplasms and thus are included in this chapter.

32.2 Clinical Presentation

The presenting signs and symptoms of various scalp and skull lesions in children are quite similar, regardless of the primary pathology. The most common complaint is a visible or palpable mass. Congenital lesions may be noticed at birth by the examining physician or the parents. Birth-related swelling of the scalp may obscure a congenital lesion or cephalohematoma that will

later become obvious. Newborns and infants with high-flow vascular malformations may have signs of high-output heart failure, including failure to thrive and cardiac murmurs.

Some lesions are painful or tender to palpation. In preverbal children, pain may be expressed as irritability or failure to thrive. Careful neurologic examination is important, but newborns and infants may harbor surprisingly large intracranial masses and still exhibit a neurologic examination findings appropriate for their chronological age. Head circumference remains one of the most valuable measurements in the assessment of young children. Abnormal tufts of hair, discoloration of the scalp, and palpable skull defects may all present for neurosurgical evaluation at various ages. In older children, it is important to determine whether the lesion has changed in size or character recently. Not uncommonly, patients are referred by a general pediatric surgeon or dermatologist after lesions previously thought to be confined to the scalp have been found to extend through the calvaria.⁷

32.3 Diagnostic Studies

Most children referred to a neurosurgeon for the evaluation of a scalp or skull mass undergo imaging with computed tomography (CT) or magnetic resonance (MR) imaging. Ultrasound, however, is frequently used as a screening examination in

Table 32.1 Masses of the scalp and skull

Etiology	Lesion
Congenital	Aplasia cutis congenita Dermoid cyst/dermal sinus tracts Atretic meningocele/meningocephalocele Nevus sebaceus
Neoplastic <ul style="list-style-type: none"> • Benign • Malignant 	Neurofibroma Osteoma, osteoid osteoma, osteoblastoma Fibrous dysplasia Ossifying fibroma Giant cell tumor Aneurysmal bone cyst Melanotic neuroectodermal tumor of infancy Neuroblastoma Lymphoma Ewing sarcoma Osteogenic sarcoma
Posttraumatic	Calcified cephalohematoma Growing skull fracture (leptomeningeal cyst)
Vascular	Hemangioma Sinus pericranii Arteriovenous fistula/cirroid aneurysm
Inflammatory	Langerhans cell histiocytosis Lymphadenopathy Necrobiotic nodules (benign rheumatoid nodules/ subcutaneous palisading granulomas) Myofibromatosis Cranial fasciitis Osteomyelitis

newborns.⁸ Indeed, some form of neuroimaging is recommended for all but the most obvious of extracranial masses. Up to one-third of patients evaluated for a solitary nontraumatic lump on the head have some degree of intracranial extension.³ Occasionally, a predominantly intracranial process, such as a subdural empyema or even a brain tumor, may present with scalp swelling, especially in infants.³

Midline or pedunculated scalp masses should be evaluated with MR imaging to assess the degree of intracranial extension and any relation to the dural sinuses. For smaller scalp lesions, the abnormal area should be marked and called to the attention of the radiologist before scanning. MR imaging is generally preferable to CT for evaluating soft tissue masses and the diploic space of the skull. CT is superior for bony masses. The two imaging modalities, however, are frequently complementary (► Fig. 32.1a,b and ► Fig. 32.2).⁸ Many skull and scalp lesions are not well visualized on routine axial CT. Vertex skull lesions are obscured on axial images tangential to the lesion, so direct coronal or thin-section cuts with three-dimensional reconstruction are necessary for improved visualization. CT protocols should be specific for children to limit the radiation dose.⁹ Radionuclide bone scans should be reserved for lesions whose imaging characteristics are suggestive of possible multifocal pathology (e.g., Langerhans cell histiocytosis, Ewing sarcoma).

32.4 Surgical Concepts

In children with scalp or skull tumors, surgery is indicated for the decompression of neural structures, curative or palliative resection, correction of disfiguring deformities, relief of pain, or biopsy of an unknown lesion. Given the low complication rate of craniotomy for the resection of skull lesions, total excision is generally performed rather than biopsy.² It is not the intent of this chapter to describe specific surgical techniques, but rather to provide an overall framework for approaching the surgical management of these patients. All resective procedures should be planned in anticipation of a reconstructive procedure. It is the authors' belief that the psychosocial effects of a cranial defect or a cosmetically disfiguring scar on a developing child, as well as the attitudes of others toward the child, should never be minimized.

In many cases, the defect left by the resection of a skull tumor may be repaired primarily with a split-thickness bone graft taken from adjacent cranium. Accordingly, the scalp incision should be designed to allow maximum vascularity as well as access to potential donor craniotomy sites (► Fig. 32.3d and ► Fig. 32.4c). Despite its length, the standard coronal scalp incision is frequently the best choice. In situations in which poor wound or graft healing is anticipated (e.g., when radiation or chemotherapy is indicated), the reconstruction should be delayed until healing conditions are optimized. This may help avoid the loss of both donor and recipient grafts due to poor wound healing and/or infection.

The need for intradural exploration is usually apparent from the preoperative imaging studies. Although most scalp or skull tumors do not demonstrate intradural extension, congenital lesions such as dermoid sinuses frequently have a definite connection to the underlying brain that must be appreciated. Failure to completely excise a dermal tract may allow growth of the

residual intracranial component or result in delayed infection.¹⁰ Missed intracranial extension¹¹ and postoperative adhesion of the brain to overlying dura¹² have been reported to cause focal neurologic symptoms analogous to spinal cord “tethering.” Thus, intradural exploration should be performed when transdural extension is apparent. The presence of dural enhancement does not always necessitate opening of the dura. Many full-thickness skull lesions incite an inflammatory response in the dura, and neuroimaging reveals a “tail” of dural enhancement (► Fig. 32.3c). At the time of surgery, the tumor is often peeled off the outer dural layer, leaving the inner intact.

32.5 Lesions of the Scalp

Congenital lesions of the scalp are quite common, but actual neoplasms of the scalp are rare in children. Typical melanocytic nevi are common on the scalp.¹³ They are usually acquired, and although they may change with time, they rarely become suspicious for malignancy during childhood.¹⁴ Congenital melanotic nevi, on the other hand, are less common but require closer scrutiny for potential malignant transformation.¹⁵ Giant congenital melanotic nevi, sometimes called congenital hairy nevi, may occur anywhere on the skin, including the scalp. They are particularly distressing for families because of their conspicuous appearance. When these lesions involve the scalp or overlie the dorsal spine, abnormal collections of melanocytes may be observed in the underlying brain and meninges.¹⁶ The potential for intracranial or intraspinal proliferation in these situations is unknown. Congenital melanocytic nevi may be further classified as “compound” when the lesions involve both the dermis and epidermis. These nevi may give rise to basal cell carcinoma or malignant melanoma.¹⁷

Another type of congenital nevus requires special attention because of its known potential for malignant degeneration. Nevus sebaceus is a congenital hamartoma primarily of the sebaceous glands that may undergo transformation to basal cell carcinoma or other, more benign skin tumors.^{18–20} It appears as a hairless, slightly raised, pink or tan area, usually on the scalp but at times on the face or elsewhere. Traditionally, resection of these lesions has been recommended both for cosmetic reasons and to decrease the risk for future malignancy.^{17,18,21} The risk for malignant transformation may, however, be less than previously suspected, and therefore the timing of resection can be flexible.²² In large lesions, staged resection may be required, and scalp tissue expansion may be necessary for reconstruction after resection.²¹

In practice, dermatologists and plastic surgeons usually treat superficial lesions confined to the dermis; it is not until subgaleal or cranial involvement is apparent that neurosurgical consultation is obtained. The following conditions, although not necessarily neoplastic, are frequently encountered by pediatric neurosurgeons.

32.5.1 Scalp Nodules

Subcutaneous nodules of the scalp are common in children. Most do not extend intracranially.²³ Lesions of the midline, painful lesions, or masses that on palpation are found to be fixed to the skull may require further neurosurgical evaluation.

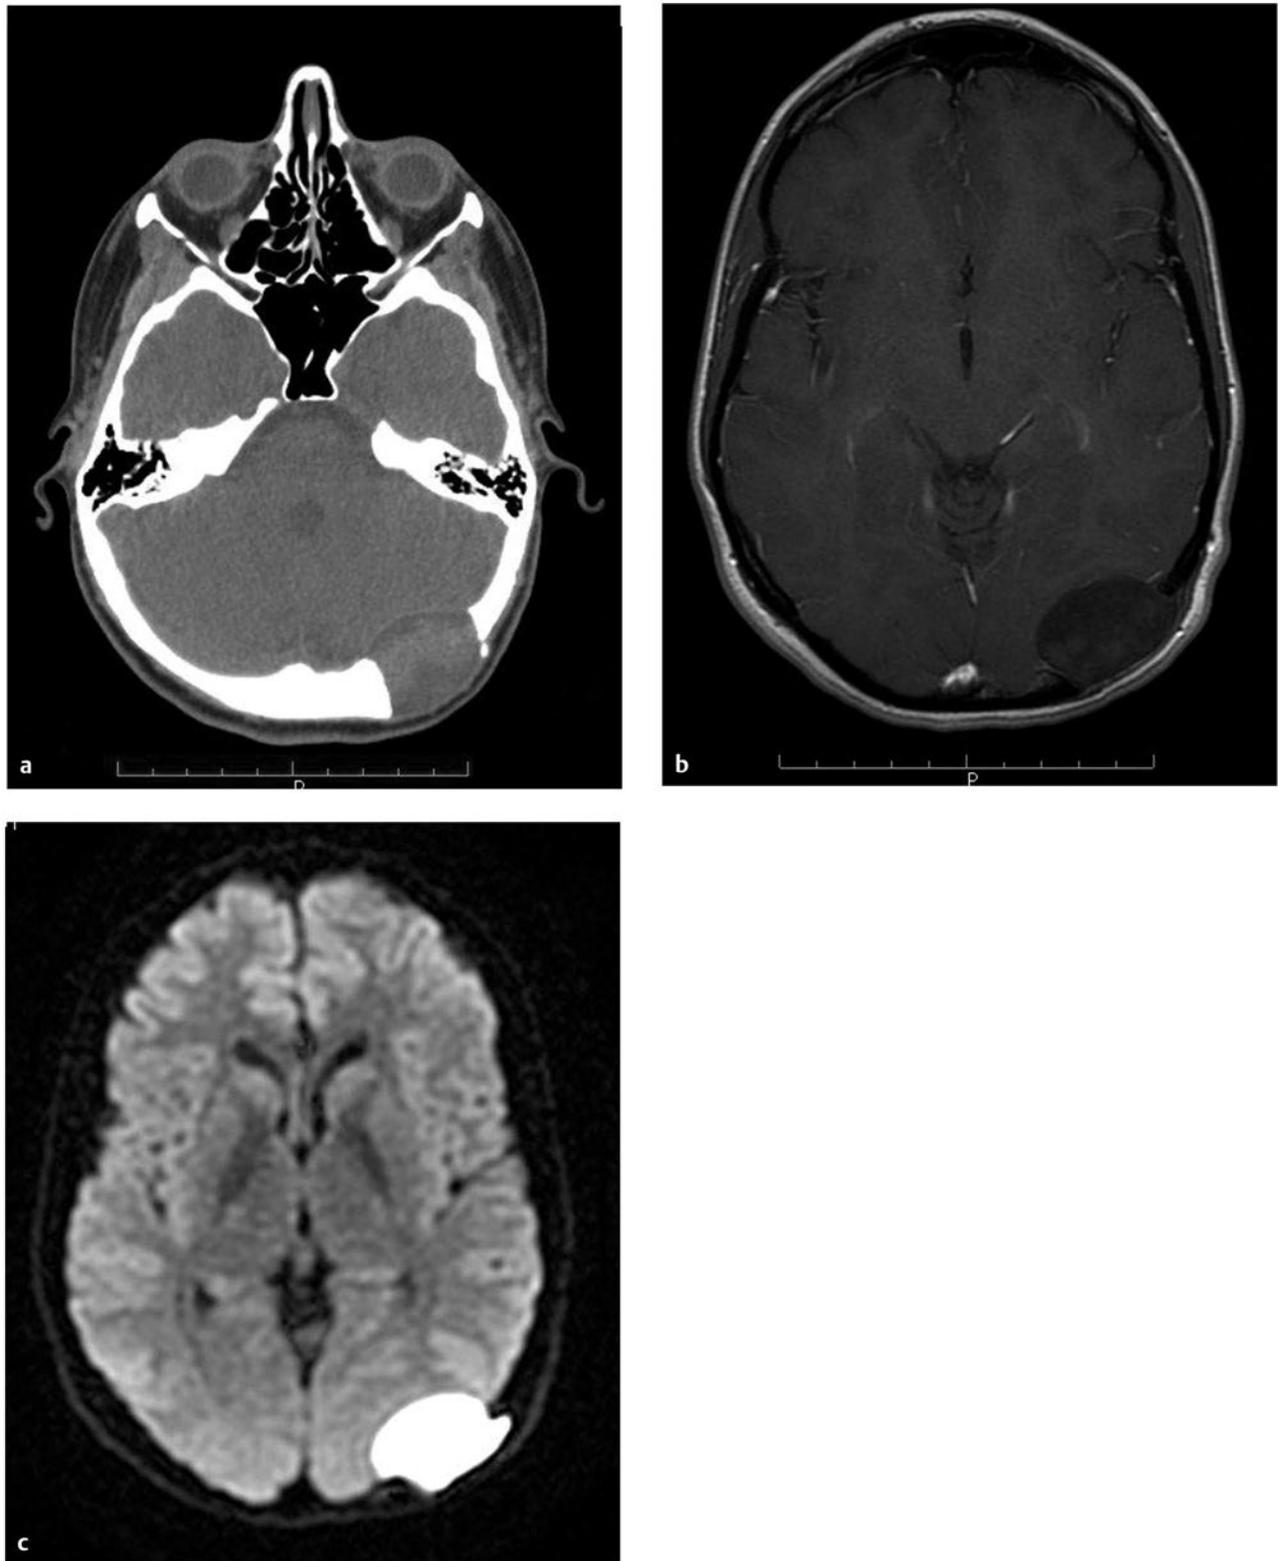

Fig. 32.1 Skull dermoid. This young adult presented with a history of a lump on the back of her head for as long as she could remember. (a) Computed tomography demonstrates a full-thickness skull defect. (b) T1-weighted magnetic resonance (MR) imaging with contrast shows a large nonenhancing occipital mass hypointense to normal brain. (c) Diffusion-weighted MR imaging reveals restricted diffusion, consistent with a dermoid cyst.

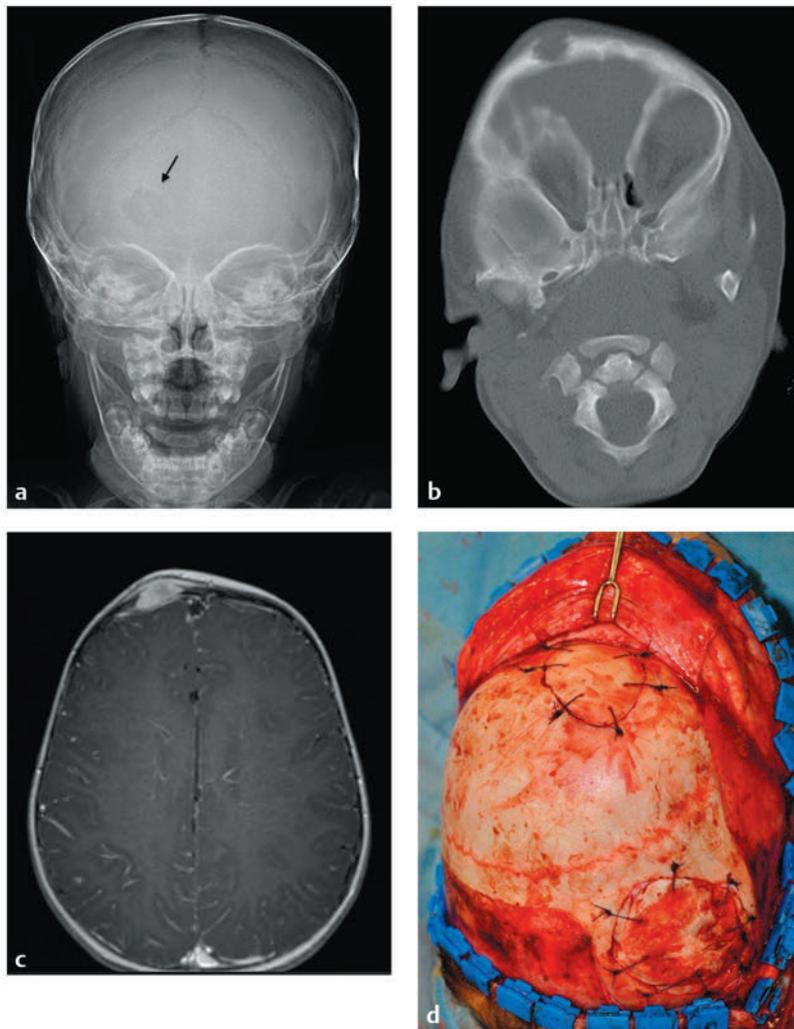

Fig. 32.2 Langerhans cell histiocytosis. This 18-month-old girl presented with swelling over the left side of the forehead. (a) Skull X-ray shows a lytic lesion with irregular but not sclerotic margins. (b) Computed tomography with bone window. (c) Axial T1-weighted magnetic resonance imaging with contrast shows marked enhancement. The lesion failed to resolve over 6 months and was completely resected. Pathology was Langerhans cell histiocytosis. (d) At the time of resection, primary reconstruction with split-thickness autologous cranial bone was performed.

Scalp nodules result from numerous processes. In children especially, enlarged lymph nodes may present as scalp nodules, particularly in the postauricular region. Lymphadenopathy appears as firm, rubbery, mobile nodules, which may be tender. There is frequently a history of upper respiratory infection, and the lymphadenopathy is self-limited. After trauma, it is not uncommon in children to notice very firm nodules fixed to the skull, with or without skull fracture. These periosteal reactions should also resolve spontaneously.

Scalp nodules associated with a tuft of abnormal hair frequently have a stalk, which may penetrate the skull to a variable extent. Although they are often assumed to represent a dermal sinus tract, these lesions may actually prove to be *heterotopic neural nodules*.²⁴ These malformations are most likely part of a continuum of developmental pathology that includes atretic meningocele, cephalocele, and encephalocele, as well as dermal sinus tracts. The location is usually midline or para-midline in the parieto-occipital regions. Despite an underlying bony defect, no intracranial pathology is usually identified apart from a persistent falcine sinus.²⁴ As a practical matter, knowledge of the histology in this clinical setting may differentiate heterotopic neural nodules from dermal sinus tracts, thus decreasing

concern regarding the need for intradural exploration and continued observation.

Neurofibromas of the scalp may accompany neurofibromatosis type 1 (NF-1) and to a lesser extent neurofibromatosis type 2 (NF-2).²⁵ With an incidence of 1 in 3,000 live births, NF-1 is a commonly observed condition in pediatric neurosurgical practice.²⁶ In a patient with NF-1 or NF-2, the discovery of painless, subcutaneous nodules of the scalp does not usually present a diagnostic problem. Occasionally, however, a nodule may be found in the absence of known neurofibromatosis. Characteristic cutaneous markings such as café au lait spots and axillary freckling should be sought, although they may not yet be present in young children. Biopsy of a lesion that shows neurofibroma, although not usually essential, will prompt consideration of the diagnosis of neurofibromatosis. Resection of neurofibromas of the scalp may be indicated when lesions are painful (e.g., in proximity to the occipital nerve) or disfiguring. Biopsy or resection should be considered in neurofibromas that have rapidly enlarged because malignant degeneration is possible. Plexiform and diffuse neurofibromas may present as disfiguring masses in the scalp and face.²⁷ Because of the diffuse nature of these lesions, complete resection is often impossible. When

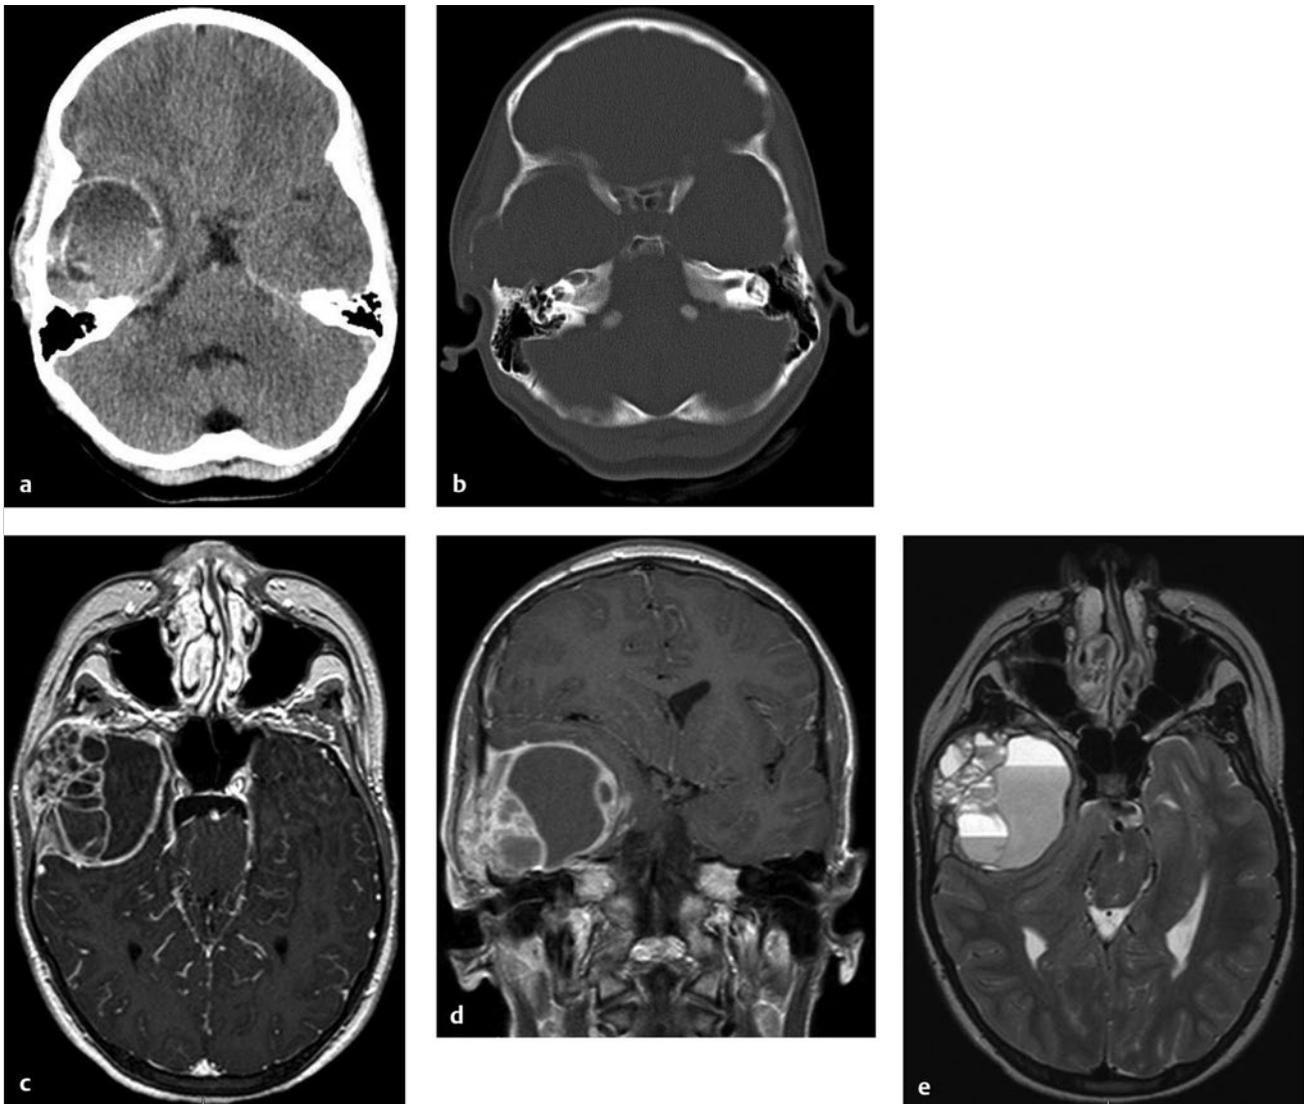

Fig. 32.3 Aneurysmal bone cyst. This 12-year-old girl presented with a nontender firm mass in the right temple. (a,b) Computed tomography shows calcification surrounding the lesion; bone windows show a thin shell of intact bone externally. (c,d) Axial and coronal T1-weighted images with contrast reveal an enhancing soft tissue portion of the tumor. (e) Axial T2-weighted image shows typical fluid–fluid levels of nonclotted blood.

indicated, subtotal debulking may be performed for large disfiguring lesions or for airway protection.

Multiple painless subcutaneous nodules of the scalp may result from an inflammatory process of unknown origin known generically as necrobiosis. Necrobiotic granulomas of the scalp are described under many titles, including *rheumatoid nodules*, *benign rheumatoid nodules*, *pseudo-rheumatoid nodules*, *subcutaneous granuloma annulare*, *xanthogranulomas*, and *subcutaneous palisading granulomas of the scalp*.^{28–30} Necrosis and degeneration of the dermal collagen are the predominant histologic features, with surrounding histiocytes and epithelioid and multinucleated cells.³⁰ In contrast to true rheumatoid nodules associated with rheumatoid arthritis, these granulomas involve the scalp and pretibial subcutaneous tissue and are not found near the joints. Progression to clinical rheumatoid arthritis does not usually occur.²⁹ The lesions have a predilection for the occipital and frontal regions of the scalp and usually resolve

spontaneously. In general, biopsy is not indicated in typically appearing lesions.^{28,29} Necrobiotic xanthogranuloma may be associated with a systemic disease such as multiple myeloma. A single case with dura-based intracranial lesions has been reported in an adult.³¹

Fibrodysplasia ossificans progressiva is a rare genetic inflammatory disorder that commonly presents with scalp nodules in infancy.³² The disease is characterized by progressive heterotopic calcification of the soft tissues, which may be stimulated by trauma or surgery. Thus, biopsy or excision may be contraindicated.³³ Patients with fibrodysplasia ossificans progressiva nearly always have a characteristic deformity of the great toes, and a definitive diagnosis can be obtained by genetic testing.³⁴ When surgery is indicated, specific anesthetic and perioperative considerations are recommended.³⁵

Despite the benign nature of the majority of scalp nodules in children, the potential for the development of malignant lesions

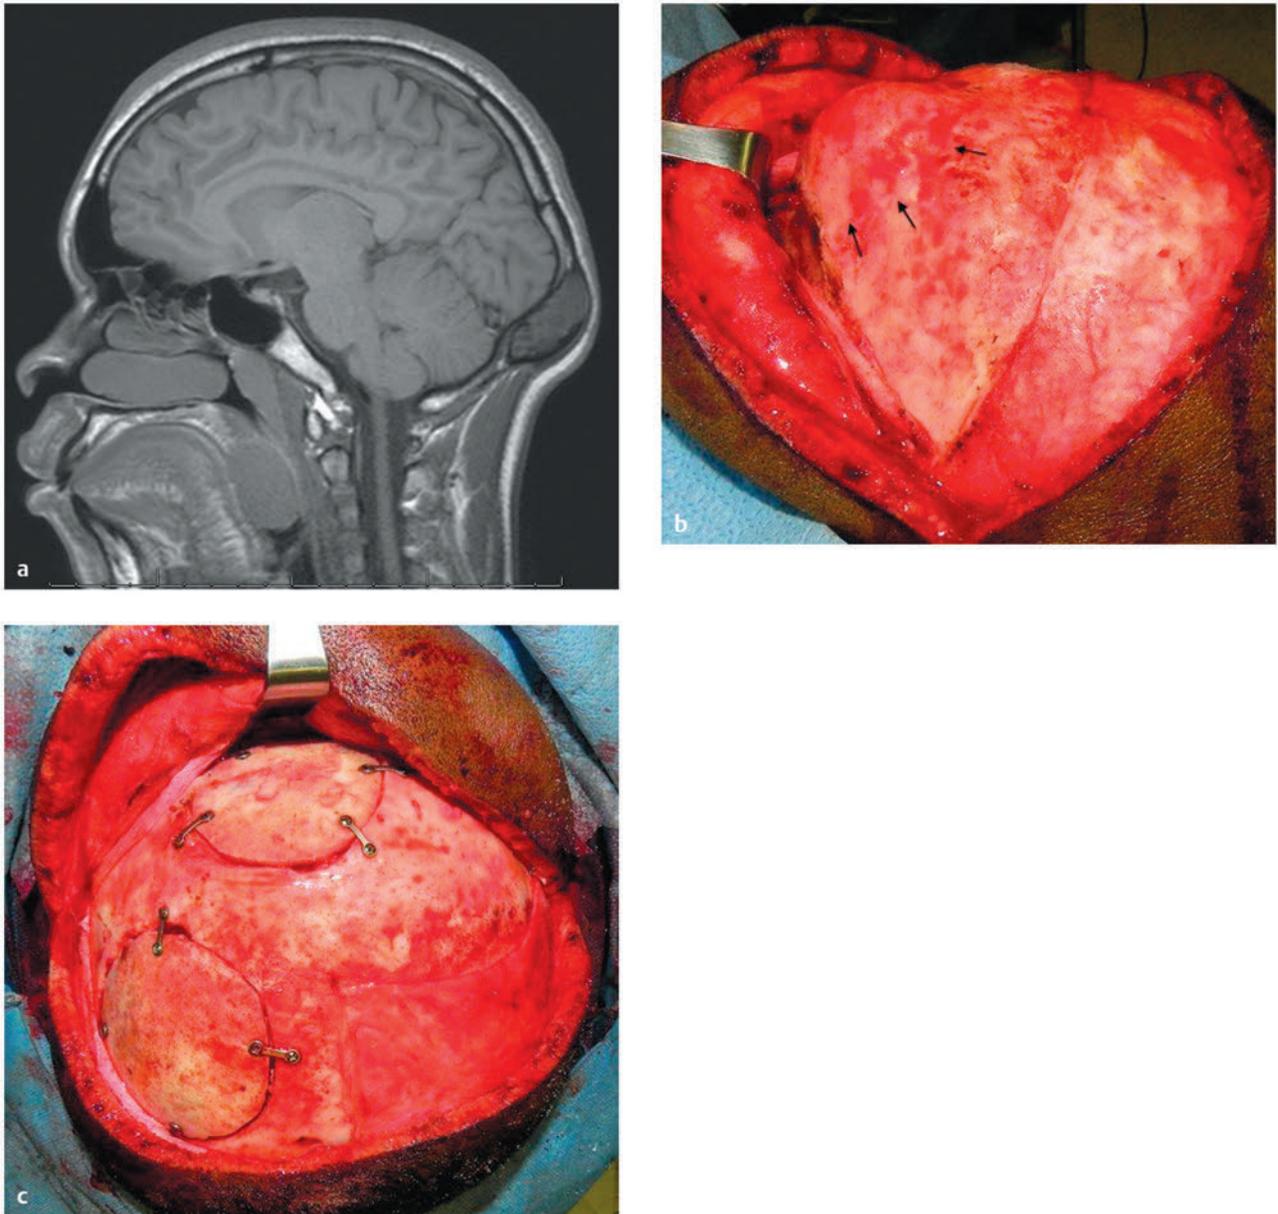

Fig. 32.4 Fibrous dysplasia. This 17-year-old young man presented with a long-standing occipital mass that had recently enlarged and became tender. (a) Sagittal T1-weighted magnetic resonance image showing isointense expansile calvarial lesion in the region of the inion. (b) Intraoperative photograph of lesion. (c) Intraoperative photograph showing reconstruction with split-thickness autologous cranial bone.

that require aggressive treatment should not be overlooked. Essentially any pathology that can affect the skin can involve the scalp. The diversity of pathologic conditions affecting the scalp is beyond the scope of this chapter, but as neurosurgeons we remain aware of the ability of the hair-bearing scalp to conceal pathologic lesions.

32.5.2 Mesenchymal Tumors

A variety of benign proliferative disorders of mesenchymal tissue occur in infancy and may result in masses involving the scalp, skull, and occasionally the dura. These lesions have

variable histologic appearances and generally have excellent long-term prognoses despite initial periods of alarmingly rapid growth. Biopsy and excision are generally performed for diagnosis and decompression. Definitive diagnosis depends on the histopathologic features, including the results of immunohistochemical studies.³⁶

Infantile myofibromatosis is a mesenchymal proliferative disorder resulting in fibrous tumors of the skin, subcutaneous tissue, muscle, bone, and viscera. Sixty percent of lesions are present at birth and 88% appear by 2 years, making this the most common fibrous tumor of infancy.³⁷ It may occur as a solitary tumor (*myofibroma*) or as multiple tumors

(*myofibromatosis*). Solitary myofibromas often occur in the head and neck and may involve the skull.^{38–43} Some lesions appear to arise from the dura and result in a significant intracranial mass effect, although the brain and arachnoid are not invaded.³⁹ Interestingly, the literature contains multiple reports of the spontaneous regression of infantile myofibromas, many of which reportedly occurred after biopsy.^{44–48} The reliability and time course of possible regression have not yet been defined, so that surgical excision is generally undertaken. If at operation dural invasion is observed, dural resection may be required.^{39,40} After complete resection, recurrence is rare, and adjuvant treatment is not indicated except in the case of multiple lesions involving the viscera.⁴⁵

The histology of infantile myofibromatosis is characterized by two populations of cells: myoid spindle cells and perivascular cells comparable to hemangiopericytoma cells.^{40,41} There are rare reports of *intracerebral* myofibromas, usually occurring in patients with multiple lesions.^{48–50} It is postulated that these rare intracerebral tumors in the setting of infantile myofibromatosis may derive from the perivascular population of cells.^{48–50} This finding is consistent with the concept of a spectrum of infantile myofibroblastic lesions consisting of infantile myofibromatosis, infantile hemangiopericytoma, and possibly congenital infantile fibrosarcoma.^{51,52}

Cranial fasciitis of childhood (CFC) is a relatively rare, benign scalp mass consisting of an abnormal proliferation of spindle cell fibroblasts in a myxoid stroma.³⁶ Initially described in 1980, CFC is now considered a subset of the more common nodular fasciitis, distinguished—as its name indicates—by a cranial location and childhood presentation.⁵³ CFC usually presents by 2 years of age as a firm, rubbery, nontender mass firmly attached to the skull, most commonly in the temporal region. The lesion is presumed to arise from the deep fascia or periosteum. These masses may grow rapidly and to alarming dimensions. Occasionally, the lesion grows predominantly intracranially, and although usually dura-based, it may rarely be purely intraparenchymal.⁵⁴ CT generally reveals an enhancing osteolytic lesion with sclerotic edges. MR imaging also shows enhancement, but with a central nonenhancing component. The enhancing region is presumed to represent the fibrous component and the nonenhancing region the myxoid matrix.⁵⁵

The etiology of CFC is unknown, but it may have a reactive component. Up to 15% of cases are associated with trauma.^{56–59} Other cases have been reported after radiation therapy⁶⁰ and at sites of prior craniotomy.⁶¹ Recently, a subset of CFC has been found to have molecular similarities to desmoid fibromatosis and Gardner fibroma.⁶²

Although spontaneous regression of CFC has been described, the reliability and time course remain unknown.^{63,64} Therefore, surgical resection of CFC is generally indicated for histologic diagnosis and relief of mass effect. Dural resection is usually unnecessary except in cases with a large intracranial extension.⁵⁴ Bone invasion should be treated with excision or curettage. Despite an appearance alarmingly suggestive of malignancy, these lesions usually do not recur, and even incompletely resected lesions may regress over time.^{58,59,65–67} Intralesional steroid injection has recently been reported to be effective in a single child with multiple small CFC lesions without skull erosion.⁶⁸ For lesions that are neither disfiguring nor of neurologic concern, this may be an acceptable option.

Desmoplastic fibroma is a benign tumor arising from bone and characterized by abundant collagen formation. It generally occurs in adults but has been reported in the skulls of infants and children.^{69,70} Radiographically, it appears as an osteolytic lesion, and although histologically benign, it can be locally aggressive. Complete surgical resection is recommended when possible because incomplete resection may result in local recurrence, and unlike the other fibrous lesions mentioned previously, it has not been observed to undergo spontaneous regression.^{69,70}

32.5.3 Scalp Defects

Failure of closure of the cranial neural tube results in a spectrum of anomalies ranging from massive encephaloceles to small skull defects through which the cranial meninges herniate without underlying cerebral abnormality. Small midline lesions, usually in the occipital region, are frequently referred to as *atretic cephaloceles* and are commonly seen in pediatric neurosurgical practice.¹ The lesions are soft and compressible, and they may increase in size with Valsalva maneuvers. The overlying skin is frequently thin, hairless, and discolored. Neural elements may be present within the cavity of the lesion with variable or no connection to the underlying brain. As noted in the preceding section, these ectopic collections of neural cells may present as scalp nodules, as well.²⁴ There are frequently associated structural anomalies of the brain seen on MR imaging.^{1,24}

Aplasia cutis congenita is a full-thickness skin defect that frequently involves the scalp. Lesions of variable size usually occur in the midline vertex.⁷¹ In 20% of cases, there is also a defect of the underlying skull.⁷² In severe cases, the dura may also be deficient, and the child may have a large area of exposed brain. Initial efforts are aimed at the prevention of infection, with timely coverage of the defect. Although these lesions are known to heal with dressing changes, staged procedures may be necessary with tissue expansion and skull reconstruction.

32.5.4 Vascular Lesions of the Scalp

Vascular lesions of the scalp are common in children, occurring in up to 75% of all newborns.⁷³ The most common type appears as pink to red macular lesions over the forehead, face, or nuchal regions, and it usually fades completely over the first year or two of life. Some cutaneous vascular lesions actually progress with age. Cutaneous *hemangiomas* and cavernous malformations occur predominantly in the head and neck in newborns. They typically progress during the first year of life with spontaneous, often remarkable, involution thereafter.

So-called *port-wine stains* are dermal regions containing abnormal blood vessels, usually capillaries and venules within the superficial vascular plexus.⁷³ Port-wine stains may become increasingly conspicuous with progressive deformity of the soft tissues and occasionally the underlying bone. This process appears to result from progressive ectasia of the involved vessels rather than vessel proliferation. A deficiency of normal sympathetic innervation of the involved vessels may be causative.⁷⁴

From a neurosurgical point of view, port-wine stains of the scalp and face may be markers of underlying cerebral

involvement. Five percent of patients with port-wine stains have Sturge-Weber syndrome, with abnormal pial vasculature of the ipsilateral cerebral cortex, seizures, and varying degrees of cognitive impairment.⁷³ Treatment of the cutaneous lesions is usually by argon or tunable dye laser irradiation and is dependent on cosmetic and psychological concerns in young children.⁷³

32.5.5 Arteriovenous Malformations of the Scalp

Fistulous arteriovenous communications may occur in the scalp and appear as pulsatile, compressible masses or with high-output heart failure in infants. These scalp arteriovenous malformations (AVMs) are frequently referred to as cirroid aneurysms of the scalp.⁷⁵ Most scalp AVMs, especially in children, appear to be congenital; however, up to one-third may be acquired after trauma.⁷⁶ In infants, the lesions may enlarge, thus consuming an increasing proportion of the cardiac output as well as creating marked venous dilatation throughout the scalp and face.

Contrast CT may show enhancement of the subgaleal scalp, and MR imaging with MR angiography may further demonstrate the malformation, but catheter angiography is necessary to delineate the vascular anatomy clearly. CT angiography in children should be carefully considered because of the radiation exposure. Arterial feeding and venous draining vessels are predominantly extracranial; however, a small contribution may be demonstrated from “parasitized” intracranial vessels with compression of the extracranial arterial supply.⁷⁶

The direct surgical treatment of AVMs of the scalp may be exasperating, with significant blood loss intraoperatively and an unexpectedly high recurrence rate postoperatively.⁷⁶ Modern endovascular techniques of either direct puncture or transarterial embolization with a variety of thrombogenic agents can significantly reduce blood flow or even obliterate these malformations.^{75–79} Surgery is often required to resect residual fistulas or to remove the mass of embolic material.^{75,78} Apart from blood loss, the most significant surgical complication is scalp necrosis.⁷⁶ Care must be taken not to carry the epigaleal dissection into the hair follicles of the scalp. The scalp incision should be planned based on the anatomy of the AVM as well as on the possible need for scalp flap rotation.

32.5.6 Sinus Pericranii

In contrast to scalp AVMs, the vascular lesion referred to as *sinus pericranii* is a relatively slow-flow anastomosis between extracranial and intracranial veins, usually involving the superior sagittal sinus.⁸⁰ The lesion presents as a painless swelling of the scalp, usually in the midline or para-midline. The lesion is compressible, deflates with head elevation, and refills with Valsalva maneuver or with the head in a dependent position. Like scalp AVMs, most sinus pericranii lesions appear to be congenital, although some may be posttraumatic. Sinus pericranii presents predominantly in childhood but may come to medical attention during adulthood, especially when acquired after trauma.

In most cases, sinus pericranii can be diagnosed clinically. Skull X-rays show only the skull defect, which may be quite

small. Contrast CT and conventional angiography frequently fail to adequately illustrate the lesions. Direct injection of contrast into the blood-filled subgaleal mass may be required if radiographic confirmation is desired.^{80,81} Sinus pericranii is usually adequately treated by direct surgical obliteration without preoperative embolization. The decision to operate is based on symptoms, cosmetic concerns, and fear of bleeding from the lesion, the perceived risk of which is usually greater than the actuality.⁸⁰

32.6 Lesions of the Skull

A wide variety of bone lesions present in childhood, including developmental, inflammatory, traumatic, and both benign and malignant neoplastic pathologies. Mostly, these lesions occur in the extracalvarial skeleton, with only sporadic appearances in the skull. The list of lesions is extensive, and only those pathologies with significant presence in the skull are reviewed here. The interested reader is referred to the more general reviews of bone tumors in children.^{82,83}

32.6.1 Epidermoid and Dermoid Cysts

Dermoid and epidermoid cysts are the most common lesion of the scalp and calvaria encountered by pediatric neurosurgeons; they account for about half of masses in this region.^{3,4} Dermoid cysts and dermal tracts are more likely to present in the scalp and skull of young children, whereas epidermoids tend to occur intracranially in older children and young adults. These congenital lesions are thought to result from varying degrees of failure of disjunction of neuroectoderm from cutaneous ectoderm during closure of the neural tube.

Dermoid cysts contain elements of full-thickness skin, including epithelium, hair structures, and sebaceous glands. There may or may not be a visible sinus or pit overlying the lesion. The lesions are usually first observed by the parents in the newborn period. Occasionally, a small cyst may enlarge or become infected, prompting evaluation. Growth occurs as epithelial cells desquamate and break down, producing an accumulation of keratin and cholesterol. The most common location in children is at the anterior fontanel, where there is rarely dural penetration.⁸⁴ Many experienced surgeons forego neuroimaging of lesions in this location except in unusual situations. Dermoid cysts also occur along sutures, usually without dural penetration. However, dermoid cysts of the occipital midline often have some degree of intracranial involvement, and MR imaging is recommended.¹⁰ MR images should be obtained with diffusion weighting, which reveals restricted diffusion (► Fig. 32.1c). Even when neuroimages fail to show intracranial penetration, exploration frequently shows a slender tract extending through the cranial bone and attaching to the dura. In these cases, the tract may simply be coagulated and divided, and intradural exploration is usually not indicated because of the relationship to midline dural venous sinuses.¹⁰

32.6.2 Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is an abnormal proliferation of cells similar to Langerhans cells normally found in skin and

lymph nodes.⁸⁵ Although the proliferations are clonal, current thinking regarding etiology is shifting from neoplasia to defective immune regulation.⁸⁶ An inciting stimulus is as yet unidentified. LCH has an incidence of 8 to 9 per million per year in children.⁸⁶ In the past, depending upon the extent of involvement, LCH was variously known as eosinophilic granuloma, Hand-Schüller-Christian disease, or Letterer-Siwe syndrome. In the aggregate, these forms were also known as histiocytosis X. Langerhans cell histiocytosis is the current preferred terminology.

LCH usually appears before puberty, typically in children 4 to 12 years of age.⁸⁷⁻⁸⁹ The clinical presentation of LCH is extremely variable. Most bones and virtually any organ, including the brain, may be affected.^{88,89} Risk is based on classification into single-system LCH and multisystem LCH (Minkov). Single-system disease may be uni- or multifocal. The most frequent site of involvement is the skull; the child typically presents with a painful mass and often with a history of recent growth or antecedent trauma.⁹⁰ LCH of the skull base also occurs and may present more of a diagnostic dilemma. Temporal bone lesions can present with symptoms resembling those of otitis media or mastoiditis.⁹¹ Lesions of the clivus may present with abducens nerve palsies, which in children may appear as abnormal head position.⁹² Dural sinus thrombosis caused by compression from an occipital LCH lesion may lead to symptoms of pseudotumor cerebri.⁹³

Skull radiographs show a radiolucent, “punched-out” lesion without sclerotic margins (► Fig. 32.3a). CT of the skull defines intracranial extension, which is usually minimal (► Fig. 32.3b).⁹⁴ The lesion is characterized by low intensity on T1-weighted MR images and high intensity on T2-weighted MR images.⁹⁵ LCH lesions enhance markedly but inhomogeneously.⁹⁵ A tail of dural enhancement and enhancing reactive change in the overlying galea and muscle is a common finding not indicating invasion (► Fig. 32.3c).^{95,96}

Although unifocal involvement of the skull is common, it is important to rule out involvement at other sites. Multifocal bone involvement occurs in 28% of children and 20% of adults.⁸⁷ Radiographic skeletal survey and radionuclide bone scan appear to be complementary for the evaluation of polyostotic disease.⁹⁷⁻⁹⁹ Bone scan better detects lesions in the ribs and vertebrae, and skeletal X-rays are more accurate for the skull and long bones.⁹⁷ Cerebral involvement is often heralded by diabetes insipidus, and hypothalamic lesions may be seen on MR imaging.^{99,100}

The treatment of unifocal LCH of the skull usually consists of complete, full-thickness excision of the lesion.¹⁰¹⁻¹⁰³ There is rarely underlying dural penetration. Reconstruction of the defect with autologous split-thickness cranial bone from adjacent skull is easily performed at the time of primary resection. Biopsy and curettage have been recommended, but without clean bone margins, the healing of a bone graft may be impaired. Complete resection is associated with a low recurrence rate, and adjuvant treatment is not usually indicated.¹⁰¹⁻¹⁰³ Although surgical treatment is generally undertaken, spontaneous resolution of skull lesions has also been documented.¹⁰⁴ Thus, some authors recommend a period of observation to see if spontaneous resolution occurs.^{87,89,104} Enthusiasm for conservative management may be tempered by the possibility of hemorrhagic complications arising from cranial LCH lesions.^{105,106} It is also

unclear if persistent lesions predispose to disseminated disease.^{107,108} Recently, LCH in the orbit, mastoid, or temporal skull region has been classified as “central nervous system risk” because of an increased frequency for the development of diabetes insipidus and other endocrine abnormalities or parenchymal brain lesions.¹⁰⁹

Surgery for LCH of the long bones is often avoided because of the risk for instability. Thus, there is more experience with the nonsurgical management of lesions in these locations. Success has been demonstrated for local steroid injection¹⁰⁸ and for a wide variety of systemic therapies and low-dose radiation therapy.⁸⁶

Disseminated or multisystem involvement, patient age younger than 2 years at diagnosis, and hepatosplenomegaly or thrombocytopenia are poor prognostic factors.^{87,89} Recurrent or progressive disease may be treated with low-dose radiation or chemotherapy. Stereotactic radiotherapy may prove beneficial for focal skull base lesions.⁵⁰ Chemotherapeutic regimens for high-risk patients are actively being developed.^{109,110}

In keeping with the unknown etiology of LCH, the natural history of the disease is also not clearly understood; likewise, the influence of current therapeutic modalities is not well defined. Surgery, radiation, and chemotherapy have not been shown conclusively to affect outcome. The reported occurrence of new bone lesions in children is 22%, and the local recurrence rate after treatment is 6%.⁸⁷ Recurrence is usually seen within 2 years of the diagnosis; in adults, recurrence may be years later.⁸⁷ It seems reasonable to follow children with LCH of the skull for at least 5 years with X-rays, bone scans, or both. Fortunately, recurrent or new bone lesions without extraskeletal involvement are not associated with a worsened prognosis.^{87,109,111}

32.6.3 Aneurysmal Bone Cysts

Aneurysmal bone cysts (ABCs) are tumorlike expansions of the diploic space that distort and attenuate the overlying cortical bone (► Fig. 32.42). The cystic lesions themselves are filled with blood and lined by connective tissue with giant cells and trabecular bone.¹¹² About 80% of these lesions come to medical attention before the end of the second decade of life.^{112,113} Only 2% of ABCs arise in the bones of the skull.¹¹⁴ Up to 30% may involve the spine (Novais). Most experience with ABCs has been obtained with lesions in the long bones. Of skull lesions, about two-thirds are confined to the maxilla or mandible.¹¹⁴ Presentation in the skull usually involves a painful expanding mass.¹¹⁵ Cranial neuropathies may be present if the lesion is in proximity to the cranial nerve foramina.¹¹⁶ These tumors may grow to considerable size, especially in infants, and may present with raised intracranial pressure.^{117,118}

Although the etiology of ABCs is not known, nearly one-third of the lesions in the long bones are considered “secondary” to other bone lesions, such as giant cell tumors and osteoblastomas.^{112,113} A similar association has been observed in ABCs of the skull⁶⁷ with additional primary pathologies, including LCH and fibrous dysplasia.¹¹⁷⁻¹¹⁹ Thus, although the radiographic appearance of these lesions may be characteristic, a diligent pathologic search must be made for any accompanying lesion.

ABCs have a distinctive radiographic appearance, with expansion but not destruction of the cortical bone and fluid-fluid levels within the cysts themselves (► Fig. 32.2e). Although they

may expand intracranially, they do not penetrate dura. ABCs are vascular lesions, and direct operation in children is frequently associated with significant blood loss. Preoperative angiography is thus often indicated, with the consideration of embolization.

Treatment is usually surgical, after embolization. Complete resection is the goal, followed by primary reconstruction. Curettage of residual abnormal bone along margins that are not safely resected is acceptable. However, in long bones, curettage alone is associated with a recurrence rate of up to 60%.¹¹³ For this reason, and considering the association of ABCs with other bone lesions, close postoperative radiographic surveillance is recommended. Residual or recurrent lesions usually respond to radiation therapy, with its inherent risks.¹¹³ Cryosurgery reduces rates of recurrence after primary surgery and offers an alternative to radiation therapy when recurrent disease is treated.¹¹³ However, application in the cranium has not yet been reported. In cases in which the risk of operative resection is considered too great, the direct injection of acrylic sclerosing agents has been reported to be effective.¹²⁰

32.6.4 Osteoma, Osteoblastoma, and Osteoid Osteoma

Osteomas are seen mostly in young adults and rarely in children.^{121,122} They arise from mature cortical bone and have a distinctive CT appearance of a hyperdense, expansile lesion without bony destruction. MR imaging is variable in these tumors and thus of limited use.¹²³ If the lesion is asymptomatic and without cosmetic significance, observation is acceptable. It is not known whether simply drilling these lesions to achieve a normal contour is associated with a significant rate of recurrence. We prefer complete resection and repair with a split-thickness cranial bone graft, for which the recurrence rate is low.¹²²

By contrast, osteoblastoma occurs more frequently in children.¹²⁴ Despite the ominous suffix, osteoblastoma in children is usually considered benign.^{124,125} It accounts for approximately 1% of benign bone tumors, and 10 to 20% of all osteoblastomas occur in the skull.¹²⁶ Histologically, osteoblastoma is composed of immature osteoid material laced with osteoblasts. The appearance is similar to that of osteoid osteoma, but more variable calcification is seen within the lesion. Because of the variable calcification pattern, radiographs and CT may fail to render the correct diagnosis.¹²⁵ Although histologically benign, osteoblastomas may enlarge and are frequently painful. Complete full-thickness resection is recommended.^{124,125} In older patients, osteoblastomas may have a more malignant appearance with features of low-grade osteosarcoma.^{122,127}

Osteoid osteomas may occur in any bone but are quite rare in the skull.¹²² The average age at presentation is 19 years, and the lesions are painful in the majority of cases.¹²² The pain classically is dull and throbbing, more severe at night, and relieved by aspirin. The recurrence rate after complete resection is low.¹²²

32.6.5 Fibrous Dysplasia

Fibrous dysplasia is a benign disease in which normal bone is replaced by slowly growing fibro-osseous tissue. The abnormal tissue is composed of fibroblasts and collagen interspersed with

immature woven bone.¹²⁸ The process begins within the medullary cavity of the affected bone and expands, thinning and distorting the cortical bone.¹²⁹ Involvement may be confined to a single bone (monostotic) or include multiple, usually contiguous bones (polyostotic). As the area of dysplasia grows, the dysplasia appears to be able to cross suture lines into adjacent bones.¹³⁰ This type of polyostotic disease is particularly frequent in the craniofacial skeleton and therefore warrants the attention of craniofacial surgeons and neurosurgeons.

Polyostotic fibrous dysplasia may occur with precocious puberty or other hypersecretory endocrinopathies—most frequently involving growth hormone, thyroid hormone, or cortisol. This association is part of the *McCune-Albright syndrome*, which may also include café au lait hyperpigmented skin lesions. Fibrous dysplasia and McCune-Albright syndrome together may represent a spectrum of disease resulting from the abnormal expression of a subtype of G proteins.¹²⁹

Fibrous dysplasia accounts for approximately 2.5% of all bone tumors.¹³¹ It appears most commonly around puberty and is distributed equally between the sexes. Although disease activity is greatest before skeletal maturation, presentation or progression may occur well into adulthood.¹³² Although progression is usually slow, more acute changes in size can occur with cystic degeneration, hemorrhage, or the unusual association of fibrous dysplasia with ABCs. Involvement of the skull occurs in up to 27% of patients with monostotic fibrous dysplasia and 50% of patients with polyostotic fibrous dysplasia.^{133–135}

The initial presentation usually involves a history of painless, progressive deformity of the skull.¹³⁰ When the orbit is involved, there may be displacement of the globe with proptosis and diplopia. The changes often occur so gradually that diplopia is unnoticed by the patient. With involvement of the bones of the skull base, the cranial nerve foramina may become narrowed. The most common cranial neuropathy results from narrowing of the optic canal. Decreased visual acuity may occur gradually or acutely.^{135–137} Temporal bone involvement may result in tinnitus, hearing loss, facial palsy, and temporomandibular joint restriction.¹³⁸

Fibrous dysplasia is best imaged with thin-section CT in the coronal and axial planes. The diagnosis is usually apparent by the CT findings of expansion of the involved bone with a “ground glass” appearance. MR imaging may be useful to evaluate intracranial extension or the relation of cranial nerves to the lesion. A grading system dividing the skull into four zones has been devised to assist with operative planning.¹³⁹

Depending on the degree of involvement, the surgical goal should be complete resection with primary reconstruction. If the entire lesion cannot be completely resected, as is frequently the case with expansion into the central cranial base, subtotal resection with decompression of the involved neural foramina should be performed. Progression of residual disease once the bulk of the lesion has been removed usually does not occur.^{130, 139} Furthermore, autologous cranial bone grafts appear to heal well and are not infiltrated by the dysplastic process when placed in proximity to residual involved bone.^{130,139} Another option is to autoclave and replace bone that would be difficult to reconstruct. Over time, this treated bone has been shown to be replaced by normal bone.¹⁴⁰ Reconstruction with dysplastic bone has even been reported, with reasonable long-term results.¹⁴¹

The issue of optic canal involvement in the setting of fibrous dysplasia deserves special consideration. Previous enthusiasm for optic nerve decompression was based on the assumption that visual loss is a result of progressive compression of the optic nerve by a stenotic optic foramen. Decompressions have been performed prophylactically as well as therapeutically for both chronic and acute visual loss. However, visual loss can occur from prophylactic decompression.¹⁴² It has more recently been postulated that the visual loss in fibrous dysplasia is multifactorial, resulting from cystic fibrous dysplasia, mucocoeles, and hemorrhage, as well as longitudinal traction on the optic nerve by bony displacement of the orbit.¹⁴³⁻¹⁴⁶ In addition, visual loss has not been correlated with the degree of optic foramen stenosis and is not necessarily progressive.¹⁴⁶ A recent meta-analysis of 27 studies examined the issue of optic nerve compression in the setting of fibrous dysplasia.¹⁴⁷ In this study, the authors reviewed a total of 368 optic nerves affected by fibrous dysplasia. All clinically impaired nerves underwent decompression, with an improvement in visual function in 67.4%. Of the clinically intact nerves, 15% were decompressed prophylactically, while the others were followed expectantly. Surgery in asymptomatic patients was associated with visual deterioration, with long-term stable vision noted in 75.6% compared with 95.1% of the nonoperated nerves. This study adds to the mounting experience that prophylactic decompression is unlikely to be beneficial in the long term. Therapeutic decompression, conversely, remains a viable option. In our experience, an extradural approach is effective and can be performed with good results and minimal morbidity. The distorted anatomy can be daunting, and when identified, the superior orbital fissure is a useful surgical landmark. Image guidance systems can be reassuring in complex cases. Physical models are helpful in conceptualizing and identifying the involved anatomy.

The goals of surgery are generally to correct cosmetic deformities and to improve or stabilize neurologic dysfunction. Additional benefit, however, may be derived from the prevention of recurrence or malignant transformation.¹³⁹ It is estimated that in approximately 0.5% of patients with fibrous dysplasia, the fibrous dysplasia undergoes malignant degeneration, usually to osteosarcoma.^{128,148} The role of radiation in this process is not entirely clear, but it may predispose to malignancy.¹⁴⁹ Therefore, radiation therapy is not recommended in patients with primary or residual fibrous dysplasia.

Other fibrous bone lesions occur in childhood but rarely involve the skull. Ossifying fibroma, also called osteofibrous dysplasia, and nonossifying fibroma are both uncommon in the skull. When present in this location, they generally involve the facial skeleton more than the cranial vault. Because of this rarity, when these lesions occur in the cranial vault they typically warrant biopsy and resection for cosmetic and functional indications.¹⁵⁰

32.6.6 Malignant Skull Tumors

As in adults, malignancies of the skull in children are usually metastatic. The histologies of these lesions are characteristic for each pediatric age group. Thus, in children with skull tumors demonstrating radiographic signs of malignancy, further studies in search of the primary source must be considered.⁸²

Small skull metastases of a known primary are usually treated with radiation or systemic chemotherapy without neurosurgical involvement. The attention of the neurosurgeon is sought when neural compression is apparent or biopsy is indicated. The previously dismal prognosis of patients with these tumors has improved markedly over the last two decades, so that the complete resection of solitary lesions, as well as planning for subsequent reconstruction, has become a potentially more rewarding endeavor.¹⁵¹⁻¹⁵³

Melanotic neuroectodermal tumor of infancy (MNTI), also known as melanotic progonoma, is an uncommon tumor considered to be derived from the neural crest. It is unique in that the lesion is grossly pigmented and thus appears black or dark purple at surgery. A review of 335 cases showed that 61% occurred in the mandible, 16% in the calvaria, and 6% in the brain.¹⁵⁴ The vast majority (>90%) of patients present in the first year of life.¹⁵⁴ Although usually benign, the tumor typically exhibits a period of alarmingly rapid growth in infancy.¹⁵⁴ In the calvaria, these tumors can be quite large and may grow inward without resulting in external skull deformities.^{155,156} MNTI of the calvaria usually appears hyperdense on CT and may be confused with hyperostosis.^{157,158} MR imaging demonstrates T1 and T2 hypointensity and may show T1 shortening corresponding to tumor melanin content.¹⁵⁵ Total surgical removal is generally curative.^{154,159} The published recurrence rate of 20% is thought to represent inadequate excision.^{154,158} Malignant MNTI accounts for 6% of cases and is disproportionately associated with brain localization.¹⁵⁴

Sarcomas

Osteosarcoma (osteogenic sarcoma) and *Ewing sarcoma* are malignant bone tumors typically occurring in older children and young adults. They are usually found in the long bones but may metastasize to the skull. Osteogenic sarcoma and Ewing sarcoma as primary tumors of the skull are quite rare.¹⁶⁰⁻¹⁶⁴ Parosteal osteogenic sarcoma is a distinct surface bone tumor that, although rare in the skull, seems to have a better prognosis than conventional osteogenic sarcoma.¹⁶⁵ With long-term survival of patients with brain tumors, postradiation sarcomas have been reported within the field of radiation.¹⁶⁶

Sarcomas in the cranium usually appear as osteolytic lesions with poorly defined margins on X-ray and CT. They are aggressive lesions, and MR imaging often reveals infiltration of the surrounding soft tissues. At the time of diagnosis, intracranial extension is frequent, and patients may present with signs of raised intracranial pressure.^{165,167} These lesions are highly vascular, and MR angiography or conventional angiography may be valuable in preoperative planning, including the consideration of arterial embolization.

Treatment consists of as complete a surgical resection as possible, followed by chemotherapy and radiation as indicated by histology and institutional protocols. Preoperative MR imaging usually indicates whether intradural exploration will be necessary as these tumors may penetrate the dura and expand along the subdural space. In general, we make no attempt at the time of primary resection to reconstruct the calvaria because healing and immunocompetence will be inhibited by subsequent adjuvant therapy. The initial scalp incision should, however, take into account the possible need for cranioplasty in the future.

Neuroblastomas

Neuroblastoma is the most common extracranial solid tumor in children.¹⁶⁸ By virtue of the number of patients involved, it is therefore the most common tumor to metastasize to the skull in this age group. Skull metastases may present as a swelling of the skull, and X-rays and CT demonstrate a lytic lesion with a characteristic “hair-on-end” appearance.¹⁶⁹ Cranial MR imaging is usually performed as part of the metastatic work-up, although intracranial metastases are rare. These metastases are rarely resected because the tumor is usually responsive to current chemotherapy regimens, depending on the clinical stage.¹⁶⁸ Operation may be indicated for biopsy of suspected recurrent disease or resection of apparently solitary disease after systemic therapy.

Leukemias and Lymphomas

Many of the various leukemias and lymphomas involve the bones of the cranium by virtue of bone marrow invasion.¹⁷⁰ Again, systemic therapy based upon histologic diagnosis and institutional protocols generally obviates the need for neurosurgical treatment.

Pearls

- Scalp and skull masses in children comprise a diverse collection of pathologic diagnoses. Congenital and inflammatory lesions are common.
- Most skull neoplasms in children are benign, and complete excision is curative.
- Patients with suspected LCH of the skull should be evaluated with skeletal radiographs for multifocal disease.
- Complete resection of fibrous dysplasia is not always necessary.
- Resection of scalp and skull lesions should be performed in anticipation of immediate or delayed reconstruction.

33 Brain Tumors in the First Two Years of Life

Nelson Moussazadeh and Mark M. Souweidane

Brain tumors manifesting in children younger than 2 years comprise a unique realm of neuro-oncology. These lesions deserve separate consideration for several reasons, all of which can profoundly impact the eventual outcome of a very young patient. Their anatomical distribution strongly favors the supratentorial compartment, whereas a predilection for the posterior fossa is seen in tumors in older children. Because of this distribution, in combination with an immature neurocognitive status, their clinical presentation is manifested not so much with neurologic findings, but rather with behavioral patterns and macrocrania of a relatively protracted and insidious duration. As a result, these tumors can achieve inordinately large dimensions before coming to medical attention and even before a correct diagnosis. Some histologic variants are so unique as to be rare in children beyond infancy. Surgical considerations that directly influence surgical morbidity include a relatively small circulating blood volume, poor thermoregulation, and incomplete skull maturity. Intraoperative adjuncts, including cortical mapping and stereotactic guidance, are rarely possible. Lastly, the therapeutic strategy needs to be tailored because of the well-recognized inverse relationship between age and potential treatment toxicity. We detail these features in this chapter, with special emphasis on the recent advances that continue to support the concept of segregating the brain tumors of very young children as a separate clinical entity.

33.1 Terminology

Previous attempts have been made to categorize young children with brain tumors according to the time of tumor genesis. Boldrey et al in 1950 proposed a definition based upon the time of symptom onset. According to this classification, children were labeled as having congenital, neonatal, or infantile brain tumors if symptoms were detected at birth, before 2 months of age, and between 2 and 12 months of age, respectively.¹ Solitare and Krigman in 1964 recognized the deficiency in this strategy because of the potential discordance between tumor origin and symptom onset.² They thus proposed that tumors be considered “definitely congenital” if symptoms were present at birth, “probably congenital” if symptoms occurred within 1 week, and “possibly congenital” when symptom onset was between 1 and 4 weeks of life. These early attempts to subcategorize and label infantile brain tumors are problematic.

In this chapter, we do not attempt to further subcategorize brain tumors in children younger than 2 years, with the exception of those tumors that are definitely congenital (i.e., symptomatic at birth). To do so presupposes an understanding of biological growth rates for varying histologic subtypes of tumors. Although it is sometimes certain that a tumor originated in utero, it is impossible to determine the time of disease onset for most children. Additionally, with any of the subclassifications outlined above, the true incidence of congenital tumors is underestimated. Spontaneous abortions and stillbirths resulting from brain tumors, estimated to account for as many as 25% of all congenital brain tumors, would not be captured in the

forementioned classification system.^{3–5} Furthermore, tumors that arise during embryogenesis, but do not become symptomatic until after infancy, would also be labeled incorrectly.

33.2 Epidemiology

Following a period of increasing incidence of pediatric brain tumors and of cancer generally from the 1960s through the 1990s related to improved radiographic diagnostics and reporting, the rate then stabilized.^{6–9} Tumors diagnosed within the first 2 years of life account for a stable proportion of childhood brain tumors, estimated at 12 to 18%.^{10–14} Pediatric brain tumors occur at an estimated frequency of about 4 per 100,000 person-years.¹⁵ Congenital brain tumors present at the time of birth or found in stillborns are relatively infrequent. Among all newborn and stillborn children diagnosed with cancer, brain tumors account for fewer than 5% cases, with a frequency of about 1.1 per 100,000 births.^{5,16} Most studies indicate a relatively equal distribution between the sexes for all tumors in aggregate, although some histologic subtypes, specifically medulloblastoma, continue to be more common in boys.^{4,17–20}

Although they account for a small proportion of children with brain tumors, infants with brain tumors afford valuable opportunities to better understand oncogenesis. That the brain tumors encountered in infancy manifest so early, with many encountered subtypes seen exclusively in this age group, suggests a strong contributory role of germline and embryonic abnormalities, and potentially fewer contributory postnatal mutational and epigenetic events. Compared with other tumors known to originate embryonically, the relatively short interval to disease symptomatology for these tumors suggests either universal penetrance with inevitable tumorigenesis or, alternatively, a scenario of high penetrance in which required Knudson “second-hit” insults are more common, are uniquely encountered, or are exclusively carcinogenic in this time period.

Genetic predisposition has been clearly established in several congenital brain tumor syndromes. For the most part, these syndromes are transmitted as autosomal-dominant traits despite the frequent harboring of mutations in tumor suppressor genes. Thus, most tumors possess biallelic loss of function manifesting as tumorigenesis. ▶ Table 33.1 summarizes the genetic locus, the gene product, and the most common type of brain tumor associated with each syndrome. What is clear from a rapidly expanding list of congenital syndromes with known genetic bases is the fact that primary brain tumors not appearing to arise by chance alone are frequently associated with a genetic predisposition to oncogenesis or mutagenesis that readily manifests systemically. However, in the absence of a recognized congenital syndrome, it currently remains inadvisable to recommend screening of the siblings or other first-degree relatives of young children with brain tumors.

Epidemiologic studies have rarely identified factors that are causally related to brain tumors in children. A multitude of potential causes have been investigated, with highly variable results and commonly contradictory conclusions. What is not

Table 33.1 Brain tumor syndromes and genetic basis

Genetic syndrome	Gene (locus)	Gene product	CNS tumor type	Inheritance
Neurofibromatosis type 1	<i>NF1</i> (17q11.2)	Neurofibromin 1	Pilocytic astrocytoma, neurofibroma, meningioma	AD
Neurofibromatosis type 2	<i>NF2</i> (22q12.2)	Merlin, neurofibromin 2	Vestibular schwannoma, meningioma, ependymoma	AD
Tuberous sclerosis complex (Bourneville disease)	<i>TSC1</i> (9q34) and <i>TSC2</i> (16p13.3)	Hamartin (<i>TSC1</i>), tuberin (<i>TSC2</i>)	Subependymal giant cell astrocytoma	AD
von Hippel-Lindau disease	<i>VHL</i> (3p26-p25)	von Hippel-Lindau protein (pVHL)	Hemangioblastoma	AD
Retinoblastoma	<i>RB1</i> (13q14.2)	Retinoblastoma protein (pRB)	Pineoblastoma	AD
Nevoid basal cell carcinoma syndrome (Gorlin syndrome)	<i>PATCHED</i> (9q22.3)	PTCH	Medulloblastoma	AD
Cowden disease (multiple hamartoma syndrome)	<i>PTEN</i> (10q23.3)	PTEN	Dysplastic gangliocytoma (Lhermitte-Duclos disease)	AD
Turcot or familial adenomatous polyposis syndrome	<i>APC</i> (5q21-q22)	APC protein	Medulloblastoma, astrocytoma	AD
Li-Fraumeni syndrome	<i>TP53</i> (17p13.1)	p53 protein	Malignant astrocytoma	AD
Rhabdoid predisposition syndrome	<i>SMARCB1</i> , <i>hSNF5/INI1</i> (22q11.2)	INI1 protein	Atypical teratoid/ rhabdoid tumor, choroid plexus carcinoma	AD

Abbreviations: AD, autosomal-dominant; CNS, central nervous system; PTEN, phosphatase and tensin

debated is the finding that ionizing radiation has been established as a cause of primary brain tumors.^{21,22} The major causes of exposure have been traced to diagnostic and therapeutic medical radiation, environmental accidents, and combat-related sources. This risk from ionizing radiation is dose- and age-dependent, with increasing doses more contributory and younger children more susceptible. Much attention and investigation have been directed toward nonionizing radiation sources (including infrared, microwave, and nearly ubiquitous radio-frequency fields, including those emanating from mobile telecommunications devices), but no conclusive evidence supports causality. Inconclusive but suggestive evidence for causality does exist for maternal and paternal dietary ingestion of cured meats, the major dietary source of *N*-nitroso compounds.²³ The implication of parental exposure to polycyclic aromatic hydrocarbons, primarily through preconceptional smoking or occupational exposure, has historically been inconclusive, but the results of large contemporary or prospective studies suggest a relatively increased risk.^{24,25} Maternal exposure to viral infections during gestation has been reported to increase the odds of a central nervous system (CNS) tumor during childhood.²⁶ Debate continues, but no strong predictive values have been found for exposure to pesticides, petrochemical products, exhaust fumes, antihistamines, and a variety of other environmental agents.

33.3 Clinical Presentation

The ability of the infant skull to compensate for volume changes, the relatively increased cerebrospinal fluid (CSF) volume within the subarachnoid spaces and cisterns, a greater degree of extracellular fluid in the parenchymal compartment,

and early developmental status all affect the timing and mode of presentation of young children with brain tumors. In short, these features combine to result in a paucity of localizing neurologic signs, delayed clinical recognition, and generous tumor sizes. The most common presenting signs in this age group are thus manifestations of raised intracranial pressure, such as increasing head circumference, irritability, lethargy, emesis, and failure to thrive.^{14,17–20,27,28} Indeed, approximately 50 to 65% of children younger than 2 years of age with a newly diagnosed brain tumor present clinically with macrocrania with diastasis of the cranial sutures and tenseness of the fontanel. Similarly, seizures are relatively infrequent, occurring in only 10 to 15% of children at presentation. It is thus understandable that many of these children are initially diagnosed inaccurately and that the discovery of the brain tumor is quite delayed from the time of symptom onset. Most studies indicate an interval of about 8 to 12 weeks from symptom onset to diagnosis, with some reports indicating several months to years before the diagnosis was reached.

33.4 Anatomical Features

The topographic features of brain tumors in infants are distinct from those of older children. First, the relationship of tumor location to the tentorium is reversed in young children in comparison with children of older age groups. A summary of several large published series with a total of 1,252 cases indicates that in children younger than 2 years of age at diagnosis, supratentorial tumors account for 63.8% of lesions and infratentorial tumors are found in 32.4%.^{14,17–19,27–29} (► Fig. 33.1). If the age group is limited to children between birth and 2 months of age

Topography of Congenital Brain Tumors

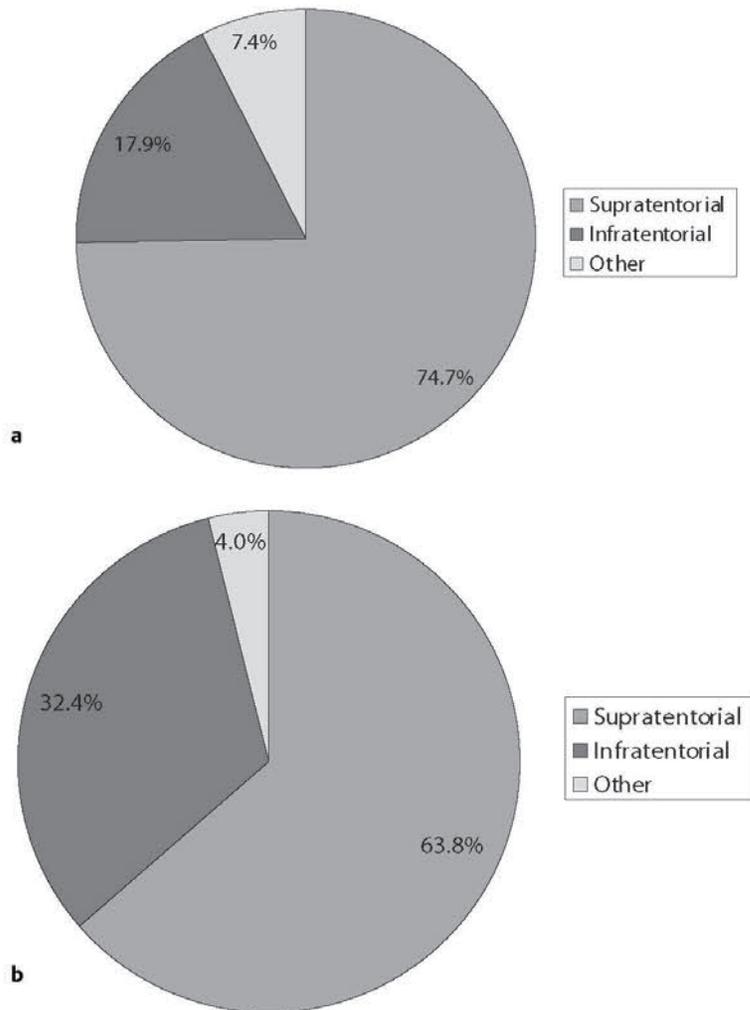

Fig. 33.1 Relative distributions of primary brain tumors in children in whom they are diagnosed before 2 years of age and in children in whom they are diagnosed at the time of birth (congenital).

at diagnosis, the distribution is further biased toward the supratentorial compartment, with 74.7% of tumors supratentorial and 17.9% located in the posterior fossa.^{3,32–34}

Another unique feature of brain tumors in very young children is their relatively large size. These tumors frequently occupy a significant portion of the hemispheric volume. In one series from The Hospital for Sick Children in Toronto, Ontario, Canada, the average maximal diameter of tumors in children younger than 1 year of age at diagnosis was 4.6 cm, with most tumors measuring between 4 and 10 cm in largest diameter.²⁰ Among 18 of 45 cases of congenital tumors reviewed in 1990 by Buetow et al, the tumor was noted to be “large, occupying more than one-third of the intracranial volume.”³² This finding was also noted by Tadmor et al in their 1980 treatise on children younger than 2 years of age with their comment that “...most of the tumors were extensive, involving more than one cerebral lobe.”²⁸ These tumors can also have characteristic cystic components that are distinct from loculate hydrocephalus. Some series indicate that the tumors of up to two-thirds of very young children have macroscopic cystic components.³² An example of these particular growth features is depicted in ► Fig. 33.2.

33.5 Tumor Types

The classification of brain tumors of infancy is based on the World Health Organization (WHO) system,³⁵ which classifies them principally according to the presumed cell of origin and degree of malignancy (grades I through IV). Although the classification system is universally used irrespective of patient age, several pathologic entities exist that remain unique to very young children and are rarely diagnosed in later childhood or adulthood. These specific tumors are found predominantly within the general categories of embryonal tumors, mixed neuronal–glial tumors, ependymal tumors, and choroid plexus tumors. Accurate diagnosis is reached through standard light microscopy, immunocytochemistry, and genetic analysis. Therefore, a detailed analysis of tumor tissue is crucial to establishing the correct diagnosis. It is clear from the experience in cooperative group studies using a central review process for pathologic interpretation that discordant diagnosis is not uncommon and potentially jeopardizes the validity of the outcome analysis.

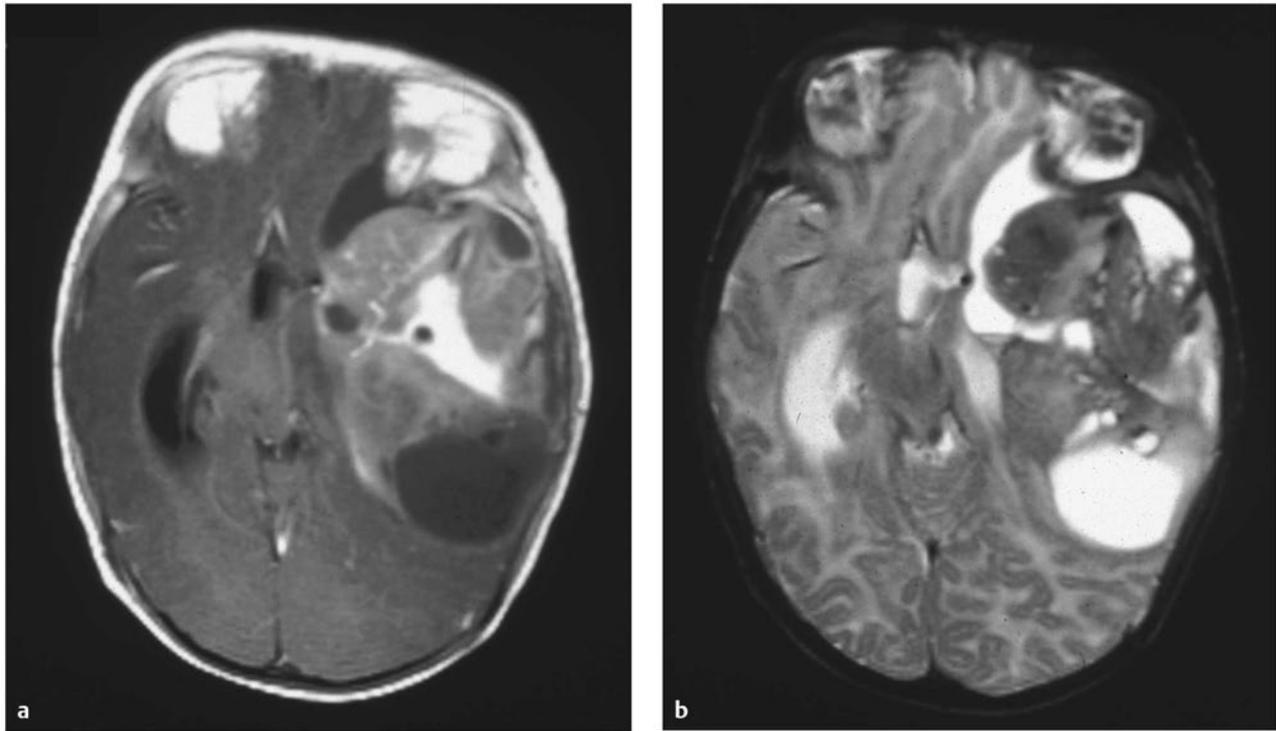

Fig. 33.2 Anaplastic astrocytoma. (a) Axial T1-weighted magnetic resonance image with contrast administration and (b) T2-weighted sequence in a 3-month-old boy who presented with failure to thrive and a divergent macrocrania. A very large mass with macroscopic cystic changes is seen in this anaplastic astrocytoma (World Health Organization grade III) of the left cerebral hemisphere. In addition to the severe mass effect, the tumor has caused ventriculomegaly, which accounts for a substantial component of the hemispheric volume.

As mentioned, the frequency of specific tumor types varies with age. The distribution of tumor types in children with a primary brain tumor who are younger than 2 years old at diagnosis is markedly different from the distribution of tumor types in older children. These relative frequencies for very young children are summarized by a review of published series cumulatively totaling 1,185 patients and are illustrated in ► Fig. 33.3.^{14,17–19,27–29}

Notably absent from these cumulative data and the large cancer registries is the atypical teratoid/rhabdoid tumor (AT/RT). The initial description of this rare tumor, accounting for approximately 1% of all pediatric brain tumors, occurred after most of the major publications pertaining to tumors in the very young had been published.³⁰ The majority of these tumors were most likely previously classified as primitive neuroectodermal tumor (PNET) or medulloblastoma in the period before 2000, when AT/RT was added to the WHO classification system.³⁶ In a French registry of pediatric brain tumors, 7 of 267 tumors in patients ages 0 to 4 years were AT/RT, versus 4 of 750 in patients ages 4 to 19 years.³¹ In an Austrian registry of pediatric WHO grade III or IV tumors, AT/RT accounted for 13 of 75 (17.3%) high-grade tumors in patients 0 to 2 years of age, versus 6 of 236 (2.5%) high-grade tumors in children ages 2 to 14 years.³⁷ The rate of diagnosis of AT/RT is significantly greater than that indicated in ► Fig. 33.3 and that indicated in large registries quantifying brain tumors in the first 2 years of life.

The major diagnostic categories of tumors in children younger than 2 years of age are described below. When appropriate, the

reader is referred to the corresponding chapter for that particular tumor. Here, we highlight the main features of each of the major histologic subtypes that are unique to infants and provide a more thorough assessment of the tumors that are particular to very young children and are seldom diagnosed beyond infancy.

33.6 Emerging Developmental Insights into Tumorigenesis

Oncogenesis has classically been understood to fundamentally represent the dysregulation of processes controlling cellular proliferation, longevity, and respect for surrounding tissues. A growing body of scholarship has established that co-opted processes of normal development frequently contribute to oncogenesis; indeed, in many tumor types, cancer stem cells embodying populations of aggressive cells capable of initiating or repopulating tumors harbor features of prematurity. Given their young age at presentation, it is therefore unsurprising that putative tumor cells of origin intimately associated with developmental progenitors have also been identified among CNS tumors of infancy.

The prototypical example of this is medulloblastoma of the cerebellum, a structure particularly susceptible to tumorigenesis because it undergoes a significant proportion of its development postnatally. Medulloblastoma comprises at least four subgroups that are biologically distinct on the basis of molecular signature, clinical behavior, and response to therapy; these include the sonic hedgehog (SHH), correlated with the

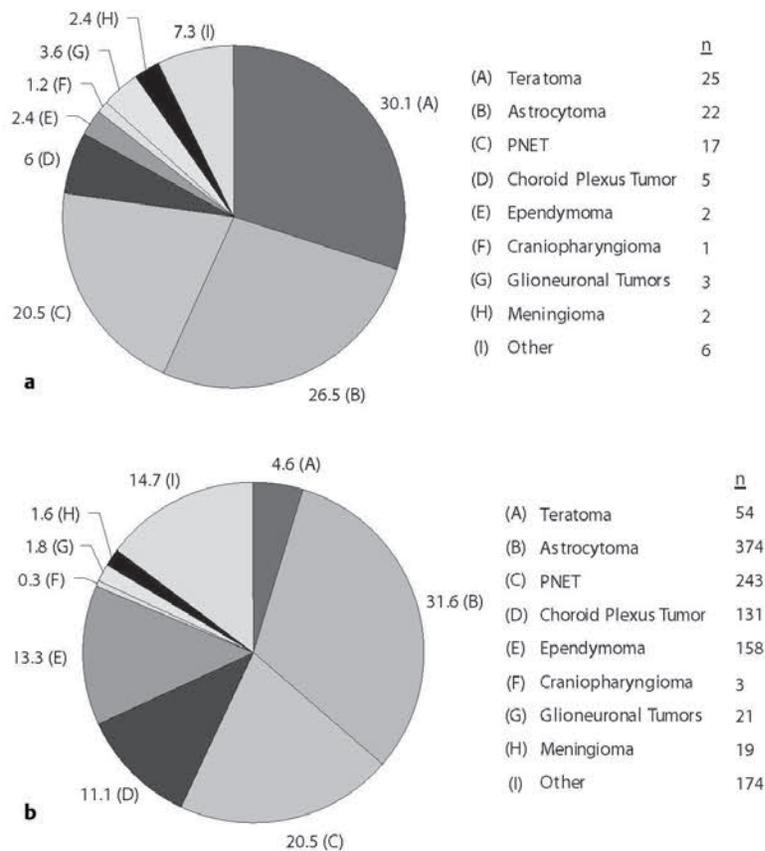

Fig. 33.3 Relative frequencies of tumor types in patients with tumors diagnosed (a) at the time of birth (congenital) or (b) within the first 2 years of life.

desmoplastic histologic variant), wingless (Wnt), and other “non-Wnt/non-SHH” genetic subtypes.³⁸ SHH-subgroup medulloblastoma, the most common subtype encountered in infants, has been shown to arise from cerebellar granule neuron progenitor cells. During normal development, granule neuron progenitor cells undergo massive expansion before cell cycle arrest and terminal differentiation in response to decreasing paracrine SHH as they migrate beyond SHH-secreting Purkinje cells en route to the internal germinal layer, where their quiescent progeny reside as granule neurons. In disease, this subgroup exhibits aberrant signaling of SHH, associated pathways including Notch, and downstream effectors of proliferation in addition to other oncogenic abnormalities.³⁹ Other cerebellar progenitors may similarly be responsible for medulloblastoma tumorigenesis, with recent evidence that those originating in the upper and lower rhombic lips may provide tumor cells of origin for some Wnt-subtype tumors.⁴⁰ These insights have already potentially yielded therapeutic targets such as hedgehog inhibitors, and advances in developmental and tumor biology may accelerate future prognostic and therapeutic progress.⁴¹

33.7 Primitive Neuroectodermal Tumors

33.7.1 Medulloblastoma

Medulloblastoma is the most common brain tumor in infants, accounting for nearly 50% of newly diagnosed brain tumors in

children younger than 2 years of age. Of all medulloblastomas diagnosed in children, 25 to 35% occur in children younger than 3 years of age.⁴² As expected, children with these tumors primarily present with symptoms of intracranial hypertension secondary to hydrocephalus resulting from fourth ventricular obstruction (► Fig. 33.4). Medulloblastomas tend to carry a worse prognosis in children younger than 2 to 3 years old. The cause of the unfavorable prognosis in this age range is speculated to result from the avoidance of radiation therapy, although some suggestion has been made that medulloblastoma in very young children may have a more aggressive biological behavior. Furthermore, leptomeningeal dissemination has been reported to be present in 27 to 43% of younger children, although this higher rate of metastatic spread is not found in all retrospective series.^{43–45}

The histopathologic grading of medulloblastoma indicates that some prognostic significance is achieved by subclassifying these tumors, although commonly used treatment regimens do not currently stratify patients on the basis of pathologic interpretation. The 2000 WHO classification recognized four separate varieties of medulloblastoma: classic medulloblastoma, desmoplastic medulloblastoma, large cell/anaplastic medulloblastoma (LC/A MB), and medulloblastoma with extensive nodularity (MBEN).⁴⁶ (For a detailed discussion of medulloblastoma, the reader is referred to Chapter 40.) The latter entity, MBEN, has only recently been defined and warrants separate consideration, given its predilection for very young children. MBEN, although rare and accounting for fewer than 5% of

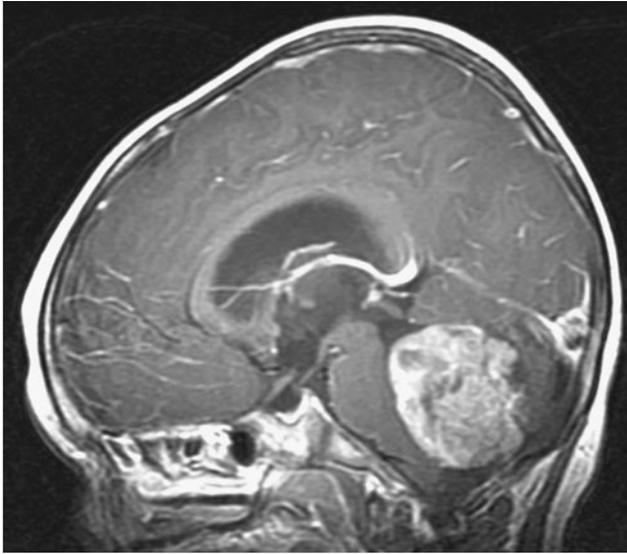

Fig. 33.4 Medulloblastoma. Sagittal magnetic resonance image following the administration of contrast in a 2-year-old boy presenting with macrocrania and intermittent morning vomiting. The fourth ventricular medulloblastoma and resulting noncommunicating hydrocephalus are easily seen on this preoperative image.

medulloblastomas, occurs most often in children younger than 3 years of age. This tumor, characterized by a cellular pattern of extensive nodular growth with strong neuronal differentiation, was formerly termed *cerebellar neuroblastoma* (► Fig. 33.5). This subtype of medulloblastoma has been shown to behave in a more indolent fashion; it metastasizes less frequently and carries a better prognosis than other medulloblastoma subtypes.⁴⁷⁻⁵⁰ However, given the challenges encountered in treating very young children and their resultant poor outcome, children younger than 3 years of age with medulloblastoma, irrespective of the extent of disease or presence of dissemination, are generally categorized as being at high risk.

The results of cooperative group studies show that the survival rates of very young children are significantly reduced compared with those of older children. The recent trend in treatment has focused on the attempt to avoid, delay, or reduce irradiation with chemotherapeutic supplementation. In a study of 12 children with medulloblastoma diagnosed before 3 years of age at MD Anderson Cancer Center in Houston, Texas, 8 children (67%) treated with chemotherapy alone had a median survival rate of 10.6 years.⁵¹ In 1993, the Pediatric Oncology Group (POG) reported a 5-year progression-free survival (PFS) rate of 32% and an overall survival (OS) rate of 40%.⁵² This study employed delayed radiation therapy (see below) and found complete surgical resection to be the strongest positive predictor. The Children's Cancer Group (CCG) employed "eight drugs in 1 day" for 46 children younger than 18 months and reported a 3-year PFS rate of 22%.⁴³ Subsequent studies by the CCG and Société Française d'Oncologie Pédiatrique (SFOP) employing conventional chemotherapy and reserving adjuvant radiotherapy for recurrent disease or as salvage treatment have borne similar outcome analyses for very young children with medulloblastoma: an expected approximately 30% PFS and approximately 40% OS at 5 years.^{53,54} Recent data published from the German

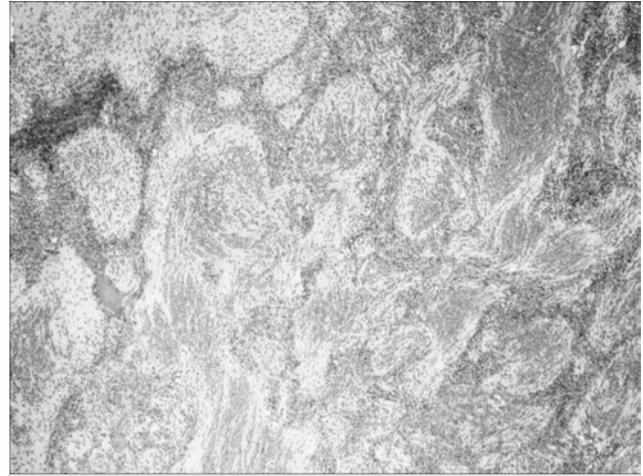

Fig. 33.5 Medulloblastoma. Low-power hematoxylin and eosin (H&E) stain of a medulloblastoma with extensive nodularity. This variant is characterized by a histologic phenotype having two major cytoarchitectural profiles. There are reticulin-free, synaptophysin-positive zones composed of well-differentiated neurocytes. These nodules are surrounded by reticulin-rich collagen regions with a subpopulation of poorly differentiated cells that do not stain for neuronal markers.

HIT-SKK87 registry noted approximately 50% and 60% PFS and OS at 10 years, respectively, in children younger than 3 years of age who were without either postoperative residual or macroscopic metastases at diagnosis and were treated with upfront adjuvant chemotherapy and craniospinal irradiation after age 3.⁵⁵

Other treatment regimens, including intensified chemotherapy and intrathecal routes of administration, have also been reported (see below). Of particular note, a recent study that utilized an intensive chemotherapeutic approach with intrathecal supplementation in children younger than 3 years of age reported favorable results.⁴²

Thus, children with medulloblastoma who are younger than 3 years of age at diagnosis are at a substantial disadvantage compared with older children in respect to overall outcome. The extent of surgical resection and degree of metastatic disease appear to influence outcome. Intensive chemotherapy and intrathecal routes are being used with increasing success to eliminate or reduce radiation exposure. Although histologic subtypes have not been effectively used to date in the prognosis or treatment of medulloblastoma, the recent description of molecular subtyping (including aberrant SHH signaling, most frequently seen in infants) and increasing knowledge of the cellular programs gone awry in the clinical syndrome will doubtless influence treatment goals, suggest avenues for drug design and delivery, and assist in tailoring therapy to an infant's individual disease.⁵⁶

33.7.2 Supratentorial Primitive Neuroectodermal Tumors

Long recognized as the hemispheric equivalent of the medulloblastoma, the supratentorial primitive neuroectodermal tumor (sPNET) clearly has a worse outcome than those

morphologically similar tumors of the cerebellum. These highly malignant neoplasms account for only 2.5 to 7% of childhood brain tumors, but they predominate in the very young.⁵⁷ In the infant population, these tumors can achieve very large dimensions and thus present an onerous challenge for surgical removal. In the 1995 summary of sPNETs from the CCG, 40% of the tumors had a maximal diameter of more than 6 cm; total resection was accomplished in only 37% of patients.⁵⁸ The POG review of sPNETs also reported the large dimensions of these tumors, with an average volume of 153.5 cm³.⁵⁹ In addition, these tumors frequently were found to involve more than one cerebral compartment, thus precluding the possibility of aggressive resection. As reported by the COG, the 5-year OS rate of 34% and PFS rate of 31% were statistically worse in children younger than 3 years at diagnosis.⁵⁸ In fact, that group showed a substantial reduction in the 3-year PFS rate from 53% for children younger than 3 years to 25% for children between the ages of 1.5 and 2 years old.⁶⁰

Some improvement in outcome has been purported with the use of dose intensification or high-dose chemotherapy and autologous bone marrow transplantation. Memorial Sloan-Kettering Cancer Center (MSKCC) reported a 2-year event-free survival (EFS) rate of 43% for 14 patients.⁶¹ In that particular series, however, 50% of the patients were older than 30 months of age at diagnosis, pineoblastoma was grouped together with sPNET, and there was a 6% treatment-related mortality rate. Among infants enrolled in the German HIT-SKK87 and SKK92 registries (ages 37 months or younger), the benefit of radiation therapy was of a magnitude (28.6% OS and 24.1% PFS among those treated with radiotherapy vs. 6.7% OS and PFS at 3 years among those with adjuvant chemotherapy alone) that prompted the authors to recommend that radiation be delayed by no longer than 6 months; however, this approach remains uncommon.⁶²

33.7.3 Pineoblastoma

PNETs of the pineal region, or pineoblastomas, are malignant embryonal tumors that arise from the pineal parenchymal cells (► Fig. 33.6). For the most part, pineoblastomas are histologically indistinguishable from PNETs in other locations. Their

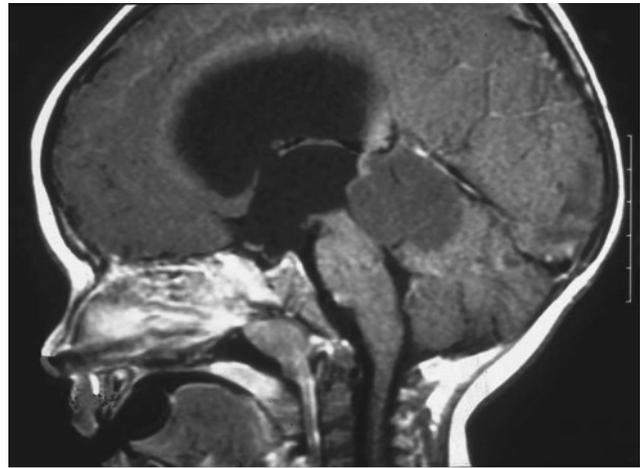

Fig. 33.6 Pineoblastoma. Sagittal magnetic resonance image following contrast administration in a 1-year-old boy who presented with macrocrania and vomiting. The lesion in the pineal region has obliterated the normal anatomical structures, causing obstruction at the level of the aqueduct and severe hydrocephalus. Histologic samples following total resection were indicative of a pineoblastoma (primitive neuroectodermal tumor of the pineal region).

behavior has been difficult to define, given the tendency to group this entity together with other malignant neoplasms of the pineal region, the historical therapeutic approach of using empiric radiation therapy, and the inaccurate assignment of the tumors to other histologic categories.

A very young child with a pineoblastoma has a significantly poor prognosis. Although justified, withholding irradiation is the most probable reason. The 1995 report by the CCG indicated widely disparate outcomes for children with pineoblastoma depending upon age at the time of diagnosis. The 3-year EFS rate for children younger than 18 months of age treated with chemotherapy alone was 0%, compared with a 3-year EFS rate of 61% for older children treated with combined radiation therapy and chemotherapy (► Table 33.2).⁶³ In the infant population, the median time to disease recurrence was 4 months, and the median time to death was 10 months. The POG reported

similarly dismal results in 11 infants with pineoblastoma when an approach of postoperative chemotherapy with the intent to delay radiation therapy was used. All patients failed chemotherapy, no patients had a response of their leptomeningeal disease, no children were salvaged with radiation therapy, and all children died of disease between 4 and 13 months from the time of diagnosis.⁶⁴

The use of high-dose chemotherapy with autologous stem cell rescue is being considered as the primary approach in young children with pineoblastoma, given the extremely poor rates of response to conventional chemotherapy without irradiation. No large cooperative study using such an approach for infants with pineoblastoma has been completed, but pilot study data indicate its feasibility. Of 13 patients with pineoblastoma recently treated at Duke University with high-dose chemotherapy and autologous stem cell rescue, two were younger than 1 year at the time of treatment.⁶⁵ These two patients, who had localized disease and underwent a complete surgical removal, had a continuous complete remission of 35 and 125 months' duration after treatment.

33.7.4 Trilateral Retinoblastoma

Trilateral retinoblastoma is a unique and particular tumor syndrome of infancy. This entity is defined as the composite of a previous history of bilateral retinoblastoma with a subsequent diagnosis of an intracranial PNET (► Fig. 33.7). Although subsequent intracranial PNET has been recognized in children with unilateral retinoblastoma, this is the rare exception. The overall incidence of an intracranial PNET, typically a pineoblastoma, in the presence of bilateral retinoblastoma is 2 to 11%.⁶⁶ The mean age of a child at the time of presentation with an intracranial tumor is about 24 months. In most reports, trilateral retinoblas-

toma has been uniformly fatal, with a mean length of survival after discovery of the intracranial tumor of 1.3 months for untreated patients and 9.7 months for treated patients.⁶⁷ The very poor outlook is partly due to the fact that up to 25% of patients have disseminated disease when the intracranial tumor is discovered. There is some evidence to support the use of neoadjuvant intravenous chemotherapy (chemoreduction) in children with bilateral retinoblastoma or a family history of retinoblastoma to reduce the incidence of trilateral retinoblastoma (► Table 33.2).⁶⁸

33.8 Ependymoma

Ependymoma of childhood is a rare tumor with an incidence of 2.1 to 2.5 per 1 million children younger than 15 years.⁶⁹ (The reader is referred to Chapter 41 for a complete discussion of ependymoma of childhood.) With a median age at onset in most large series between 36 and 52 months, the infant population represents a disproportionate fraction of children affected.^{70,71} In children younger than 2 years, the majority of these tumors are fourth ventricular in location. Ependymomas in infants are found less frequently in the supratentorial compartment, where they may be entirely intraparenchymal and have no relationship to the ventricular compartment. Those tumors arising within the cerebral hemispheres can attain voluminous sizes due to their relatively indolent growth rates (► Fig. 33.8).

A young age at the time of diagnosis has been repeatedly shown to negatively affect outcome in children with intracranial ependymoma. Proposed reasons include a lower rate of complete resection, the avoidance of radiation therapy, and biologically aggressive behavior.^{70,72} The outcome for infants

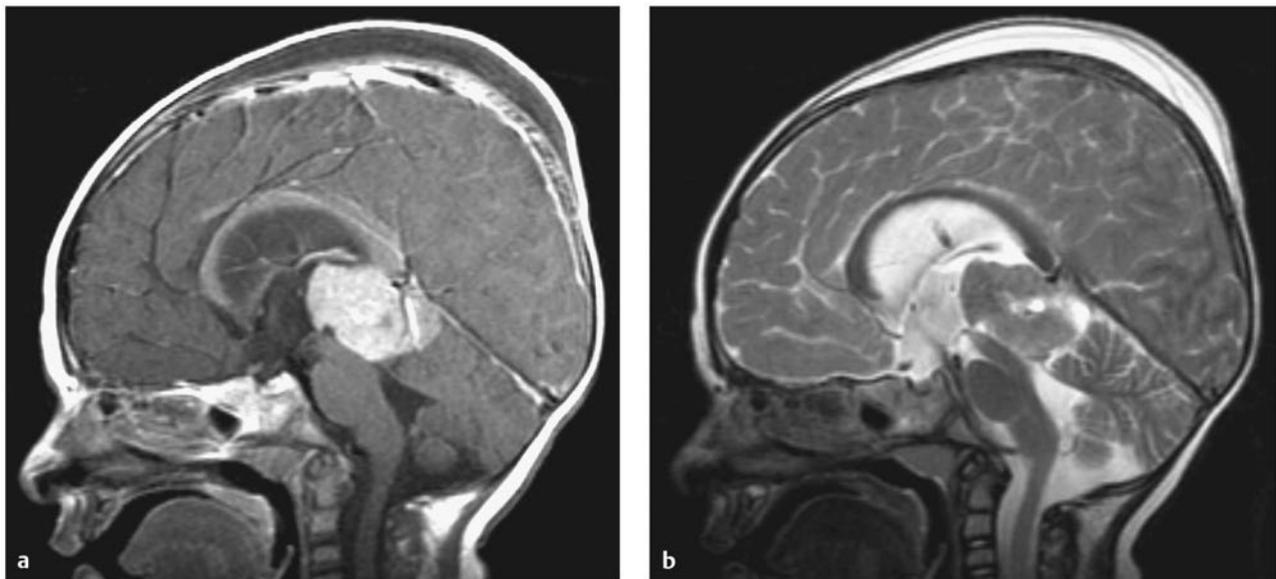

Fig. 33.7 Trilateral retinoblastoma. (a) Sagittal T1-weighted magnetic resonance image with contrast and (b) the corresponding T2-weighted sequence of an 11-month old girl previously treated for congenital bilateral retinoblastoma. The images were obtained after an endoscopic third ventriculostomy and tumor biopsy (note the turbulent flow pattern at the site of the third ventriculostomy). This child with trilateral retinoblastoma underwent total resection of a pineoblastoma following induction chemotherapy.

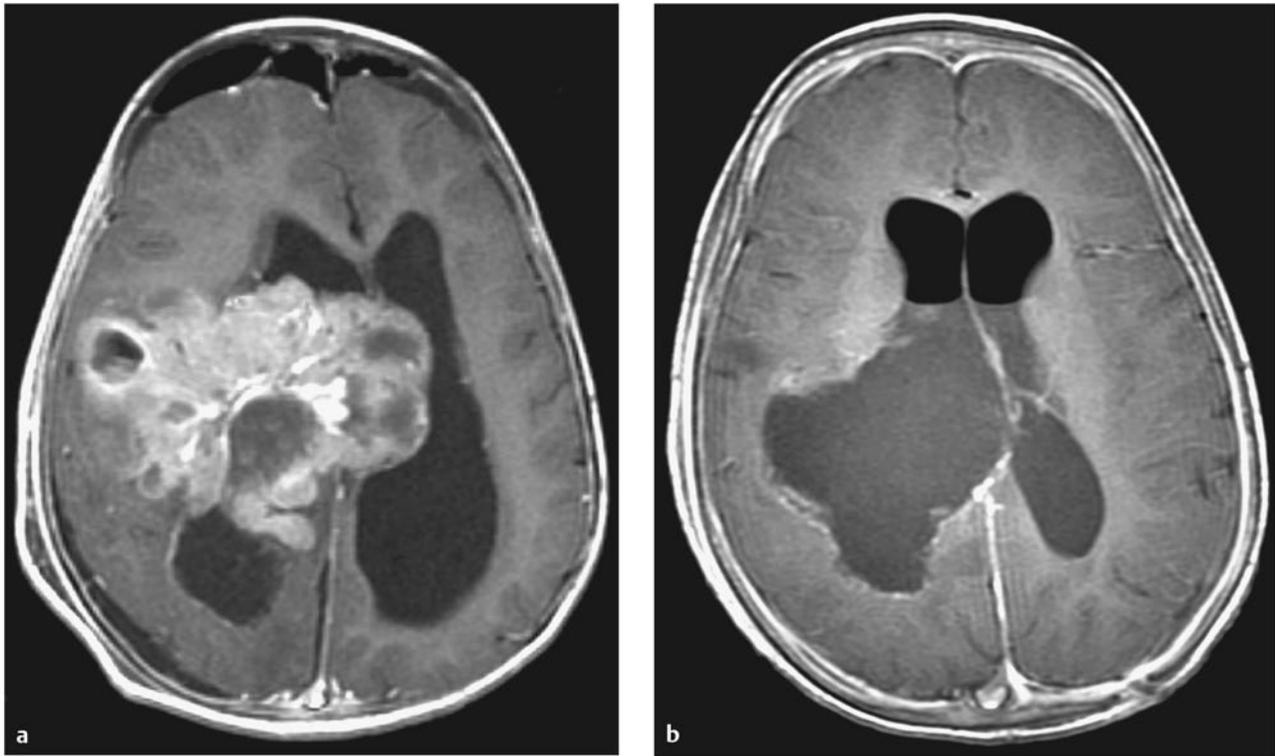

Fig. 33.8 Ependymoma. (a) Preoperative and (b) postoperative axial magnetic resonance images following contrast administration in a 14-month-old boy with a supratentorial ependymoma. The tumor occupies a significant portion of the right cerebral hemisphere. The child underwent total excision of an anaplastic ependymoma at second-look surgery following adjunctive preoperative chemotherapy.

treated for ependymoma was a 3-year PFS rate of approximately 26% as assessed by the CCG.⁴³ Although whether pathology is predictive of outcome is controversial, the CCG study enrolled only patients with a malignant or anaplastic histology. The POG evaluated 48 children younger than 3 years with ependymoma (classic and anaplastic varieties) and found a radiologic response rate of 48% with a treatment approach that used neoadjuvant chemotherapy with the intent of delaying or completely avoiding radiation therapy. The extent of resection was found to be the most important predictor of outcome, with 5-year OS rates of 66% and 25% for those children undergoing gross total excision and subtotal excision, respectively. The study also established that the disease control rates, which are similar shortly after therapy, diverge with longer follow-up between patients younger than 1 year and those between 2 and 3 years of age at the time of treatment. Thus, at 5 years, the younger patients had a 26% survival rate, whereas the older children had a survival rate of 63%. The conclusion drawn from these important observations was that a delay of radiation of more than 1 year adversely affects survival.

As is true in children of all ages, the principal site of recurrence is usually at the primary site of disease, with a minority of children having disseminated disease at the time of progression. The pattern of recurrence and poor control rates have led to the use of highly conformal radiation therapy as a therapeutic adjunct. This approach has been used in 88 patients whose mean age was 2.85 years, with 15 patients younger than 18 months at the time of treatment, at St. Jude Children's Research

Hospital in Memphis, Tennessee.⁷³ With a median follow-up of over 38 months, the 3-year PFS rate was 75%. In interpreting these data, it is important to bear in mind that 84% of the patients had confirmed gross total excision of their tumor before irradiation.

Because of the wide recognition that the extent of surgical excision positively affects outcome, other strategies, including surgical re-exploration (so-called second-look surgery), have been advocated for residual ependymoma. This approach has been used in small, single-institution series with initial success toward achieving gross total excision.^{74,75}

33.9 Astrocytoma

A detailed account of astrocytomas in children can be found in Chapters 42 and 43. However, several characteristic features of astrocytomas in very young children warrant separate consideration.

33.9.1 Optic Pathway Gliomas (Chiasmatic/Hypothalamic Gliomas)

Gliomas of the optic pathway (chiasmatic/hypothalamic gliomas) account for nearly 20% of all intracranial tumors in children younger than 2 years.⁷⁶ These children can present with several manifestations. Alterations in vision usually manifest as nystagmus, spasmus nutans, or poor fixation. Raised

intracranial pressure from noncommunicating hydrocephalus is most frequently identified by progressive macrocrania. The diencephalic syndrome of emaciation, or Russell syndrome, is quite specific for a hypothalamic glioma during infancy; it is characterized by failure to thrive, normal axial growth, and increased growth hormone levels.⁷⁷ The most frequent manifestations of alterations in endocrine function are precocious puberty and growth hormone deficiency. Although neurofibromatosis type 1 (NF1) is present in roughly half of all children with chiasmatic/hypothalamic glioma, most children younger than 2 years in whom this tumor is diagnosed do not have NF1.⁷⁸ Although the less frequent association with NF1 may in part be responsible for the poorer prognosis of children younger than 2 years of age, the tumor may have a more aggressive biological behavior in very young children, and there is a reluctance to utilize radiation therapy. The current treatment strategy includes chemotherapy only in the presence of symptom progression or radiographic changes. With such an approach, the 5-year PFS rate for children younger than 3 years of age at diagnosis has been reported at 63%.⁷⁸

33.9.2 Pilocytic Astrocytoma

A recently described variant of hypothalamic/optic pathway pilocytic astrocytoma, pilomyxoid astrocytoma has been recognized to have a predilection for younger children; the mean age at onset is 18 months.^{79–81} This subtype of pilocytic astrocytoma is identified on the basis of the histologic phenotype, but the diagnosis carries a different set of clinical features. In addition to causing symptom onset at a younger age, these tumors exhibit a more aggressive behavior, a higher rate of local recurrence, a substantial rate of CSF dissemination, and a shorter PFS (mean, 26 months) and OS (mean, 63 months).⁷⁹ The histologic identification is based on a monomorphous rather than a biphasic pattern of cells on a myxoid background. The tumor is notably absent in Rosenthal fibers and has rare eosinophilic granular bodies, features quite commonly found in the pilocytic counterpart. The recognition that pilomyxoid astrocytoma occurs predominantly in the infant age group may partly explain the well-known association between poor prognosis and young age in children with hypothalamic/optic pathway astrocytomas. At the current time, the treatment of pilomyxoid astrocytoma is analogous to that of pilocytic astrocytoma, but with better classification of this subtype, the therapeutic approach may change.

33.9.3 Supratentorial High-Grade Astrocytoma

The malignant astrocytomas (WHO grades III and IV) that occur in young children, although much less frequent, appear to be unique compared with similar histologic tumors in older children and adults. The overall outcome in children with malignant astrocytoma is more favorable in most series. However, infants with malignant astrocytoma do not possess the same prognostic advantage realized in older children. Infants with malignant astrocytoma present a treatment dilemma, not unlike infants with other supratentorial malignant tumors, owing to the large size and hemorrhagic potential of the tumor and to treatment limitations caused by adverse events related to

therapy. The CCG experience concerning the outcome of 39 children younger than 24 months of age treated with neoadjuvant chemotherapy indicated an overall response rate of 24%.⁴³ The most significant variable affecting outcome was tumor pathology, with 3-year EFS rates of 44% and 0% for anaplastic astrocytomas and glioblastomas, respectively.

Some molecular analytic data indicate that malignant astrocytomas in infants are biologically distinct. Mutations in the tumor suppressor gene *TP53* appear to be distinctly less frequent in tumors from children younger than 3 years of age than in those from older children and adults.⁸² Given that overexpression of p53 has been correlated with an unfavorable prognosis for children with malignant gliomas, this reduced incidence of mutagenesis may indicate a better response rate to particular therapies.⁸³

33.10 Choroid Plexus Tumors

Choroid plexus tumors are truly unique tumors of very young children, with the majority of patients younger than 3 years of age at the time of diagnosis.⁸⁴ Choroid plexus tumors account for approximately 0.5% of all intracranial tumors but nearly 12% of all brain tumors in children younger than 2 years of age. Hydrocephalus invariably exists in children with choroid plexus tumors. The mechanism is probably multifactorial, but this entity represents the only known common cause of CSF overproduction resulting in hydrocephalus (► Fig. 33.9). After complete tumor removal, treatment of hydrocephalus may still be needed, given the likely association with intraventricular hemorrhage or inflammatory reactions resulting from surgery and mechanical distortion of the intraventricular CSF pathways. The rate of resulting need for CSF diversion by way of shunting has been reported to be as high as 75%.⁸⁵ Subdural effusions tend to require further management nearly as frequently as hydrocephalus. The large size of the tumor, degree of ventriculomegaly, and extended duration of the surgical cases all probably contribute toward this postoperative management issue. Closure of the corticectomy site with fibrin sealant following tumor removal has shown some success in isolating the intraventricular compartment from the subarachnoid space.

These tumors are some of the most surgically challenging lesions in infants owing to their large size, invasiveness, and hypervascular nature, with intraoperative mortality not infrequently reported resulting from blood loss.⁸⁷ The surgical approach needs to be tailored such that the vascular pedicle or tributaries are identified early and controlled before the tumor is removed. Depending on the site within the lateral ventricle, a high parietal approach offers early recognition of the medial posterior choroidal vessels, whereas an inferior temporal approach offers early control of arterial feeders from the anterior choroidal artery through the choroidal fissure in the temporal horn of the lateral ventricle. Some attempts to reduce tumor vascularity preoperatively with endovascular embolization have been reported.^{86–89} These attempts have historically been limited, given the technical challenges associated particularly with cannulating the medial posterior choroidal vessels; however, when possible, the benefits are apparent and may contribute toward a simpler resection. One recent report even suggests

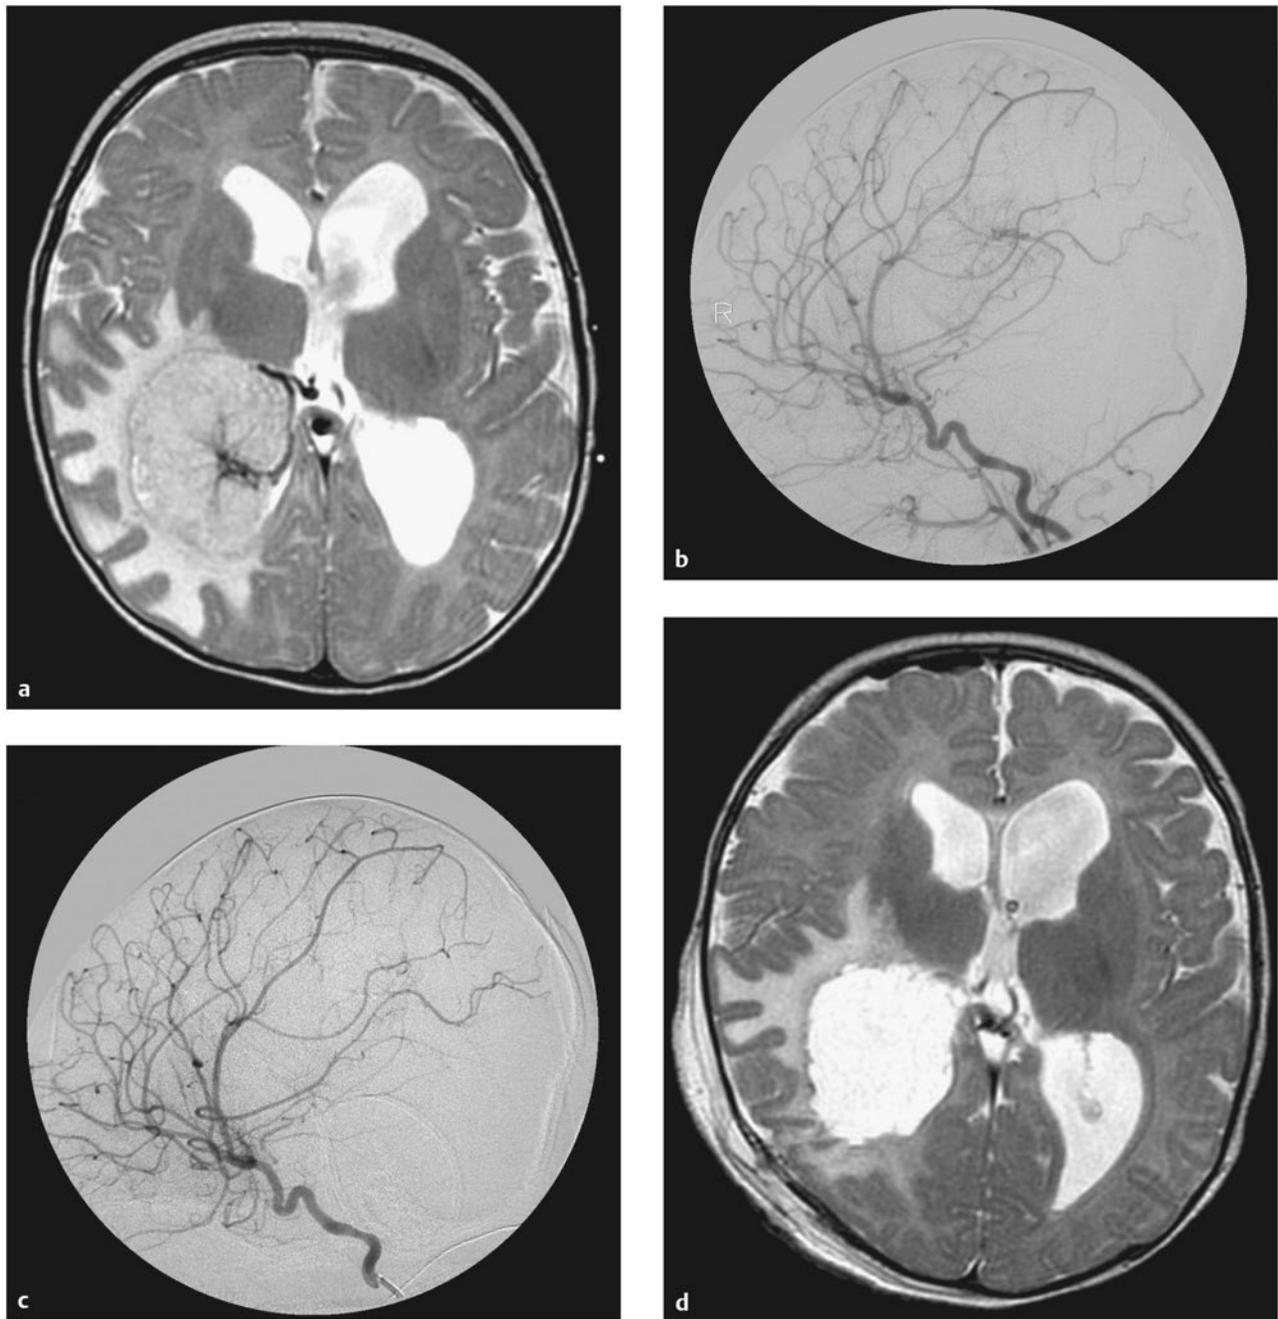

Fig. 33.9 Choroid plexus papilloma. Representative magnetic resonance images from a 4-month-old boy who was evaluated for increasing head circumference. (a) An axial T2-weighted image revealed a large left intraventricular mass and ventriculomegaly. Given the expected tumor vascularity, (b) an angiogram was obtained that confirmed the presence of a very rich arterial supply. The lateral projection of the right internal carotid artery depicts the tumor blush principally from the right anterior choroidal artery. (c) The postembolization angiogram demonstrates a reduction in vascular blush. (d) The postoperative axial T2-weighted image confirms that a gross total excision of the tumor was accomplished.

complete remission of a presumed choroid plexus papilloma by embolization alone at 16-month follow-up.⁹⁰ An example of such an approach is shown in ► Fig. 33.9.

Choroid plexus papilloma (WHO grade I) occurs about twice as often as choroid plexus carcinoma.⁸⁷ The differentiation of these tumors is based on careful interpretation of the pathologic specimen (► Fig. 33.10). Contrary to the predominantly fourth ventricular location seen in adults, the lateral ventricle is

the most common location for choroid plexus papilloma in children. These tumors are treated with primary resection, which in contemporary series is achieved in as many as 96% of cases.⁸⁷ With complete excision, the 5-year survival rate has been reported to be as high as 100%. The atypical choroid plexus papilloma (WHO grade II) is an entity of intermediate malignancy and prognosis relative to papilloma and carcinoma of the choroid plexus.⁹¹

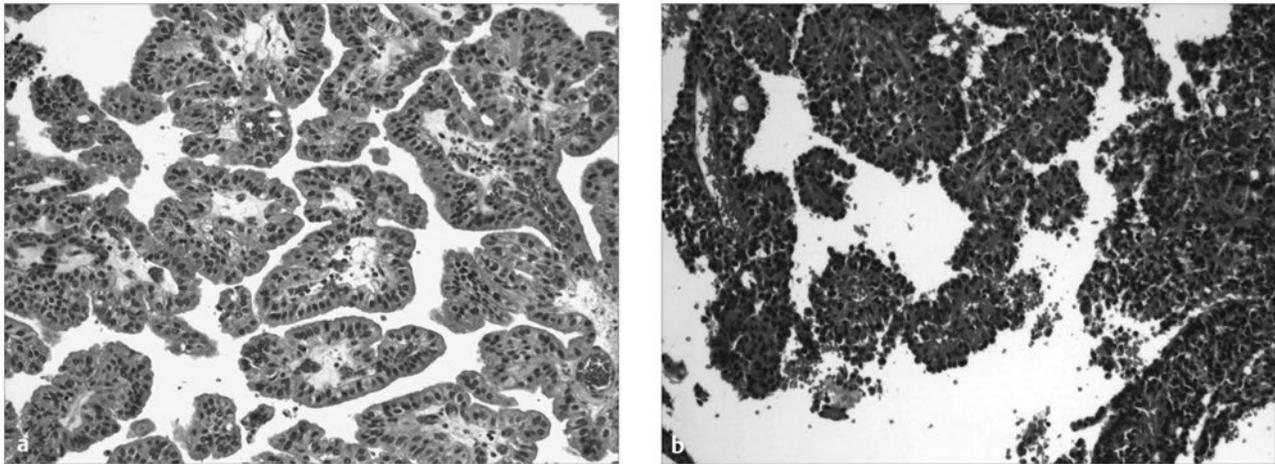

Fig. 33.10 Choroid plexus tumors. Histologic samples from (a) a choroid plexus papilloma and (b) a choroid plexus carcinoma. Both recapitulate a papillary cytoarchitecture, but the carcinoma shows foci of solid growth and prominent cytologic atypia.

Choroid plexus carcinoma (WHO grade III) is a rare disease, accounting for 1 to 4% of all brain tumors in children. This tumor differs from its more common counterpart, choroid plexus papilloma, in that it most frequently arises within the lateral ventricle, presents during infancy, is frequently invasive, and has a relatively poor prognosis. The 5-year OS rate ranges from 40 to 50%.^{92,93} Treatment modalities have ranged from surgery alone to surgery with postoperative radiation therapy and chemotherapy. Most reports suggest that the prognosis is improved with complete surgical resection^{87,92–95} and the use of adjuvant chemotherapy.^{87,93–100} Although no consensus exists about the value of chemotherapy after total excision, published response rates with measurable disease certainly indicate that there may be a benefit in this context. Complete surgical resection is hampered by the typically large size and vascularity of these tumors in young children with a proportionally small circulating blood volume. In one contemporary study, the rate of surgically related mortality due to complications of excessive hemorrhage was as high as 30%.⁸⁷ Irradiation, whose role is supported by some previous evidence, has fallen out of favor, given the typically young age of afflicted children and the known detrimental sequelae of irradiation during infancy.

Loss of function of *TP53*, implicated in a variety of tumors, as previously mentioned, and responsible for the Li-Fraumeni syndrome, has recently been shown to be associated with higher grades and poorer outcomes in the approximately 50% of sporadic and syndromic choroid plexus tumors in which it is found, compared with the intriguingly large fraction of these tumors that exhibit other alterations in this gene.¹⁰¹ While mechanistic studies are ongoing, screening for Li-Fraumeni syndrome and molecular analysis of somatic tumor tissue may play an important prognostic role in the future treatment of this disease.^{102,103}

33.11 Atypical Teratoid/Rhabdoid Tumor

Since the earliest description of atypical teratoid/rhabdoid tumor (AT/RT) as a separate entity, better clinical descriptions

have become available, and the tumor has undergone molecular characterization as well.³⁶ AT/RT frequently occurs in children younger than 2 years of age; the mean age at diagnosis is 17 months.^{36,104,105} The tumor has a predilection for the posterior fossa and pineal region; however, it also occurs with some frequency in the supratentorial compartment. In fact, the tumor occurs about twice as frequently in the infratentorial compartment as in the supratentorial location. Surgical resection is challenging owing to the hypervascular nature of this tumor, and the difficulty is compounded by the young age and relatively small circulating blood volume of the patients.

The histologic appearance reflects the malignant nature of the tumor, evidenced by a compact and highly cellular lesion with widely pleomorphic features, mitotic figures, and areas of necrosis. The small, compact cytoarchitecture is reminiscent of medulloblastoma, and it is likely that many of these tumors are incorrectly diagnosed as such³⁶ (► Fig. 33.11). A population of large, pale cells with “rhabdoid” features is responsible for the current nomenclature. The embryonic nature of the tumor is confirmed by its immunophenotypic diversity, which indicates mesenchymal and epithelial differentiation (vimentin, glial fibrillary acidic protein, epithelial membrane antigen, cytokeratins, synaptophysin, chromogranin, and smooth muscle actin).¹⁰⁶ Chromosomal and genetic analysis confirms that this tumor differs from other highly malignant embryonal tumors. Cytogenetic analysis yields the frequent loss of chromosome 22, with involvement of the chromatin-remodeling tumor suppressor gene *INI1/hSNF5* detectable in a majority of cases.^{107–111}

With multimodal therapy, the mean postoperative survival is between 6 and 11 months, usually marked by early recurrence and CSF dissemination.^{104,112} Lasting responses to multimodality therapy have been reported.^{113–117} Of the long-term survivors, most have been treated with aggressive surgical resection, radiation therapy, and chemotherapy. The chemotherapy regimen in those cases was based on a multiple-agent regimen designed by the Intergroup Rhabdomyosarcoma Study III (IRS III) for parameningeal rhabdomyosarcoma. Notably, this approach incorporates the use of both systemic and intrathecal chemotherapy. Survivors treated with this approach are reported to

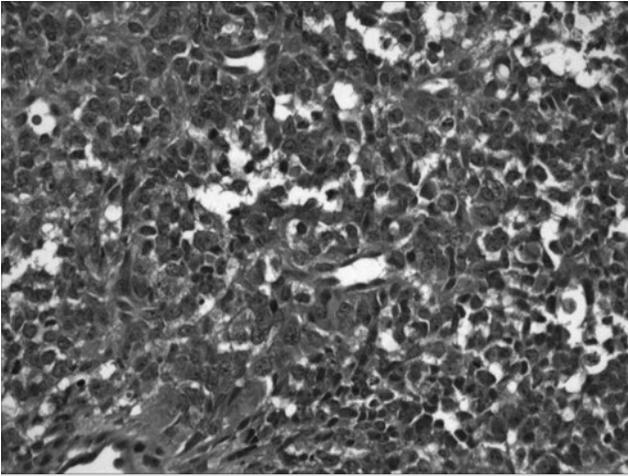

Fig. 33.11 AT/RT. Low-power hematoxylin and eosin (H&E) stain of an atypical teratoid/rhabdoid tumor. Large cells contain moderate amounts of pink cytoplasm, hyperchromatic nuclei, and prominent nucleoli. The compact nature of the tumor with a notable frequency of mitotic figures is reminiscent of a medulloblastoma. Note the large vacuoles, which produce a “starry sky” pattern.

have a mean disease-free interval of just over 3 years, with one pilot study achieving a median OS of 50 months.^{113,117}

33.12 Teratoma

Teratoma is the most common primary brain tumor diagnosed at the time of birth.¹¹⁸ There is little debate that this tumor is truly a congenital neoplasm, given the very early age at presentation, the occurrence of prenatal diagnosis, and the frequent association with stillbirth. An enlarging head circumference resulting from a massive intracranial mass is the typical presentation in children born alive. In fact, the accelerated growth characteristics have led to several reports of extension of the tumor beyond the confines of the cranial compartment.^{119,120} The histologic hallmark of this tumor is the recognition of derivatives from all three primordial germ layers (endoderm, mesoderm, and ectoderm). The tumors can be graded as benign or malignant, the latter defined by poor differentiation. The overall outcome for children with a teratoma is poor, usually because the massive size and extensive growth characteristics of the tumor make surgical removal impractical. The exception to this poor outcome is the situation in which a benign teratoma can be totally excised, in which case long-term survival is expected.

33.13 Desmoplastic Tumors of Infancy

Several tumors of infancy exist that share very similar anatomical, histologic, and biological features. These rare tumors account for approximately 1% of all tumors in infants.¹²¹ Macroscopically, they are found exclusively in the supratentorial compartment and are located superficially at the cortical surface. They variably attach to the dura, possess multiple circumferential cysts, and attain voluminous sizes (► Fig. 33.12).^{122–124} Their superficial location is manifested in a growth pattern that can

cast the gyral and sulcal patterns, creating an almost multilobular pattern.

These tumors share not only gross morphologic features but also microscopic elements (► Fig. 33.13). The most prominent characteristic is the microscopic finding of a robust desmoplastic stroma. This background of a dense fibrous connective tissue rich in reticulin fibers is reminiscent of mesenchymal tumors. Frequent mitotic figures and spindle cells that resemble those of sarcomatous tumors frequently lead to an inaccurate diagnosis and an incorrect ominous prognosis.¹²³ The tumors are generally categorized as desmoplastic infantile ganglioglioma or desmoplastic cerebral astrocytoma of infancy, depending on whether the predominant immunohistochemical pattern of staining is astrocytic or ganglionic, respectively. Owing to the somewhat unclear classification of these tumors, desmoplastic infantile ganglioglioma has been referred to as a gliofibroma, whereas desmoplastic cerebral astrocytoma of infancy has been classified as a superficial cerebral astrocytoma. Because of this varied terminology but similar clinical and histologic features, attempts have been made to aggregate these tumors into the single clinicopathologic entity of desmoplastic supratentorial neuroepithelial tumors of infancy.^{125,126}

Regardless of the nosology or descriptive histology, the biological behavior of these tumors appears to be analogous. With rare exception, they have a very indolent behavior, meaning that total surgical excision is expected to render a cure. Long-term disease-free intervals are the norm after surgical removal. The extreme sizes and cortical location of these tumors occasionally lead to incomplete surgical resection. Residual tumor can remain static without interval growth for extended periods or even involute, with a radiologically defined reduction in tumor size.¹²² This latter point emphasizes the usual lack of need for adjuvant therapy after surgery, even in the case of an incompletely removed tumor. Because chemotherapy has been reported to result in an objective tumor response, some recommend chemotherapy when total surgical excision is not possible.¹²³ These recommendations were based on a small number of patients culled from a cooperative study; their diagnosis was incorrect, and they were thus treated with therapeutic regimens intended for patients with high-grade glial tumors. The indolent behavior of the tumors and their occasional spontaneous involution without therapy suggest that it would be conjectural to infer a causal relationship between chemotherapy and tumor response in desmoplastic tumors of infancy.

33.14 Treatment

33.14.1 General Considerations

Therapeutic strategies are tailored to individual cases based on tumor location, size, histology, and the patient's clinical condition. Thus, the optimal form of treatment for infants with primary brain tumors varies substantially. The treatment of young children with malignant brain tumors is significantly more challenging than the treatment of older children or adults because of the well-recognized detrimental effects of therapeutic intervention on the developing CNS. As a result, the overall outcome for infants and young children is appreciably worse than it is for their older counterparts. The prognosis depends mainly on tumor type, but generalizations about outcome have been

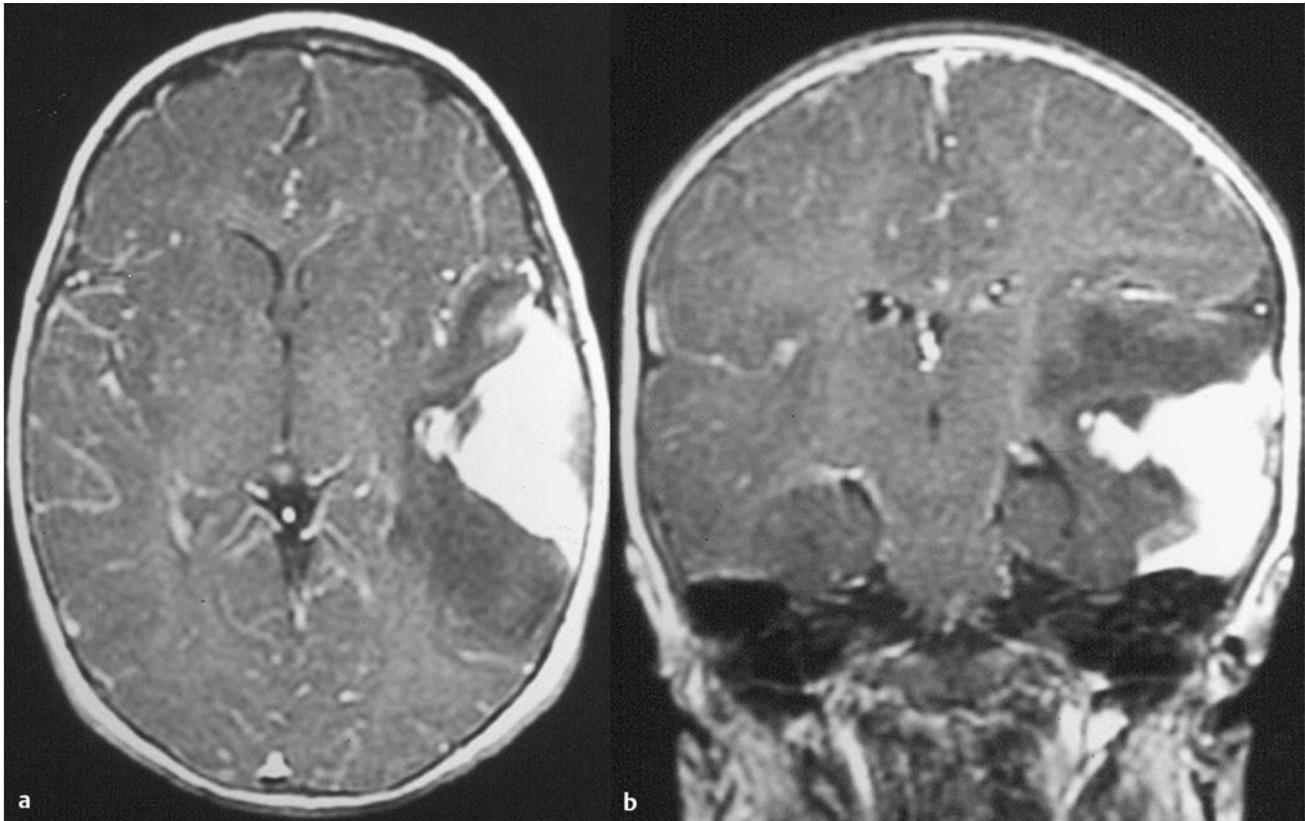

Fig. 33.12 Desmoplastic infantile ganglioglioma. (a) Axial and (b) coronal magnetic resonance images of a 5-month-old boy who presented with seizures. A supratentorial location, superficial or cortical origin, and very large size are all characteristic features manifested in this desmoplastic infantile ganglioglioma.

recognized for decades based on studies and databases that include all histologic subtypes. The Surveillance, Epidemiology, and End Results (SEER) Program indicated that in children younger than 2 years who were treated for benign and malignant tumors, the 5-year survival rate ranged from 23 to

36%.^{127,128} This dismal outcome has been attributed to a variety of causes, including less aggressive surgical resection, more aggressive biological behavior, greater metastatic potential, and intentional avoidance of radiation therapy. Several features have been implicated in the worse outcome of very young children treated for a brain tumor. Primary among these probable causes are the inability to achieve a total tumor resection because of very large tumor dimensions, relatively large blood loss, and a more infiltrative growth pattern. It has been suggested that staged surgical procedures and second-look surgery after chemotherapy offer an advantage over the aggressive surgical removal of brain tumors.

Additionally, the relatively poor prognosis for children younger than 2 years with malignant brain tumors results from the avoidance of conventional irradiation. Over the past two to three decades, the detrimental effects of therapeutic doses of irradiation on neurodevelopmental outcome have justifiably led toward the development of therapeutic protocols that integrate neoadjuvant chemotherapy with the intent to postpone or eliminate radiation therapy.^{43,52,129} High-dose chemotherapy with autologous stem cell transplantation has been reported to positively influence outcome in particular diseases. Another therapeutic design intended to replace craniospinal irradiation incorporates intrathecal chemotherapy.

Some recent concepts mandate a more detailed discussion with respect to the treatment of infants with newly diagnosed

primary brain tumors. These evolving strategies, although not universal, are based on early cooperative group trials, but most commonly on pilot study data from single-institution investigations. All of these approaches share a conceptual framework of maximizing the disease-free interval while minimizing the early or late effects of therapy.

33.14.2 Surgical Treatment

With few exceptions, the extent of surgical resection is positively correlated with overall outcome. The surgical management of young children with brain tumors significantly differs from the surgical management of older children and adults. Unequivocally, the operative mortality rate exceeds that for older children undergoing craniotomy for primary brain tumors. In contemporary series, the mortality rate has ranged from 7.3 to 33% for children younger than 2 years at the time of surgery.^{14,17,20,29} Mortality rates from surgical intervention are most commonly attributed to blood loss, and it is thus intuitive that tumor histology influences the outcome of infants undergoing craniotomy for tumor removal. This point has been elaborated on in a review of 76 children younger than 2 years, whose surgical mortality rate ranged from 0% for benign tumors to 20% for highly malignant tumors.¹⁹ However, with the use of advanced perioperative adjuncts, including preoperative magnetic resonance (MR) imaging, microneurosurgical techniques, pediatric neuroanesthesia, and pediatric intensive care unit monitoring, a 0% surgical mortality rate can be achieved.²⁷ This result is highly commendable, given that malignant tumors accounted for 50% of tumors and that total excision was accomplished in 55% of the 22 patients in that particular series. Clearly, mortality rates from surgery can be influenced by the definition used of a surgically related death and the period of time during which death is attributed to the surgical procedure. What is certain is that surgical morbidity and mortality are not insignificant, and that the operative management of these children should not be undertaken without a dedicated and multidisciplinary approach toward the treatment of infants with brain tumors.

Many features demand that standard procedures be tailored to ensure the safety of infants undergoing a craniotomy for brain tumor removal. First, the child's small size has a direct impact on temperature control and circulating blood volume. The problem of a small circulating blood volume is exacerbated by the voluminous size and hemorrhagic nature of many infantile tumors. Second, the lack of skeletal maturity introduces a risk for skull fracture and intracranial injury with standard skull fixation. Third, the immature neuronal circuitry and young developmental age limit the ability to perform intraoperative or preoperative cortical mapping. These points are elaborated upon in the following discussion, with recommendations offered for optimizing each goal while maintaining safety.

The relatively high ratio of body surface area to body weight in infants creates a situation in which convection rapidly lowers the body temperature. This circumstance is magnified by the slowed metabolic rate of the anesthetized child, the lack of an integumentary barrier within the surgical field, the infusion of intravenous fluids, the paucity of stores of yellow fat, and the cooling induced by standard preparatory scrubs. The relatively large head size of the young child also affects the ability to

maintain normothermia during intracranial procedures. Many of these issues are minimized by employing a rational and preventive approach. To reduce convective cooling, the ambient room temperature should be elevated. Thus, most neonatal surgery should take place only in operating rooms in which independent temperature control is available. A simple maneuver to help minimize temperature loss during the surgical scrub is to prewarm the preparatory solutions in the surgical incubator before use. In addition to reducing the amount of heat loss, warm air currents or convective warming blankets can be used to warm the child. Warming systems need to be used with care so as to avoid having any heating elements in direct contact with the skin. The replacement of circulating blood volume with either intravenous fluids or blood replacement products is frequent in young children undergoing resection of primary brain tumors, and all transfused fluids should be warmed before administration to help maintain physiologic body temperature.

Meticulous hemostasis, although a mandatory component of surgery, especially in infants, is not in itself a guarantee against potential poor outcomes. Thus, preparations need to be coordinated before the initiation of the surgical procedure. Intravenous access that can accommodate rapid transfusion is essential, as is continuous blood pressure monitoring with an arterial line. Appropriately cross-matched whole blood should be available in the surgical suite at the initiation of the procedure. The judicious use of bipolar cautery, hemostatic clips, and bone wax is critical. Although the hemorrhagic nature of the tumor is beyond control, the technique of tumor removal will have a bearing on the degree of blood loss. For instance, thorough coagulation of the tumor surface before debulking can reduce blood loss. Achieving control of the tumoral region receiving the dominant blood supply is also useful. The latter point is exemplified in the removal of choroid plexus tumors from an intraventricular location. Selecting an approach that affords visualization and early control of the choroidal vasculature is recommended. Although the surgical technique can clearly reduce the degree of blood loss, the nature of certain tumors makes their safe removal almost prohibitive in infants. This scenario is most notable in children with highly malignant neoplasms, such as choroid plexus tumors and AT/RTs. The circulating blood volume of neonates is estimated to be 90 mL/kg (or some 300 mL in the average child born in the developed world), that of infants 85 mL/kg (some 1 L in the average 2-year-old), and that of older children approximately 80 mL/kg.^{130,131} This awareness of total circulating blood volume can help in making decisions about staging the procedure and when to consider supplementing platelets and plasma. Although laboratory measurements of platelets and coagulation profiles can guide such decisions, blood loss equivalent to one circulating blood volume is a reliable indicator that these products should also be administered.

The fragility of the infant skull, owing to its thinness and the presence of cranial sutures, create a potentially dangerous situation for the use of rigid pin fixation, with risks including scalp laceration, calvarial fracture, and epidural hematoma.¹³² This obstacle is avoided by using nonrigid methods of fixation, such as a cushioned horseshoe head frame. However, the lack of rigid fixation diminishes or abrogates the effectiveness of surgical adjuncts such as rigid self-retaining retractors and frameless stereotaxy. Furthermore, with prolonged procedures, the additional concern of pressure necrosis of the scalp necessitates

intermittent intraoperative repositioning. The risk of pin fixation is somewhat lessened by using an increased number of pins in an effort to distribute the pressure more evenly and decrease torsional strains on the skull. Specially designed pins are available that have a reduced length and a collar to reduce the risk for transcranial migration. Depending on the expected duration of the surgery, the maturation of the child, and the expected need for intraoperative adjuncts, the decision to use pin fixation needs to be tailored. There is no general consensus on the safe use of pin fixation in young children, but a common recommendation is to avoid pin fixation in children younger than 2 years.¹³³ In very young children, the risk for cranial perforation and cranial compression is lessened somewhat by utilizing head frames that accommodate more than three pins so as to disperse pressure.

Recent attention has focused on stereotaxy adjuncts that do not rely on rigid fixation, with reports of successful navigation utilizing frameless, pinless approaches to secure a reference frame to the skull. These approaches have included the application of an affixed or adhered reference for electromagnetically based tracking and the use of beanbag-based supportive pseudofixation.¹³⁴⁻¹³⁶ Additionally, modifications have been developed for frame-based stereotactic devices, thus enabling their use for less involved procedures, such as stereotactic biopsy.¹³⁷ Practically, given that the great majority of tumors in this age group attain very large dimensions and are associated with significant hydrocephalus and/or tumor cysts, the reliability of stereotaxy based on preoperative imaging is quickly diminished intraoperatively.

Intraoperative adjuncts, including cortical mapping and stereotactic guidance, have limited use in very young children. Infants' inability to cooperate and their immature developmental status imply that cortical mapping cannot reliably or practically be used. Furthermore, extraoperative mapping by way of functional MR (fMR) imaging or intraoperative mapping with cortical bipolar stimulation is difficult and typically yields unreliable information. Some attempts at using fMR imaging in sedated children have resulted in a paradigm that works with passive stimulation techniques.¹³⁸ Most children do not exhibit cerebral dominance until at least 2 to 3 years of age; therefore, this limitation may not be as problematic as it is in older children or adults, given the known potential for cerebral plasticity during infancy.

Alternatively, transfontanel or transcortical ultrasonography can be used intraoperatively, depending upon the intended goal of navigational assistance. For navigational or directional assistance, transfontanel ultrasonography can be useful. This modality also serves as an important adjunct in infants undergoing volumetric tumor resections, and it has the added appeal of not requiring pin fixation.¹³⁹ Intraoperative MR imaging has advantages over these modalities in that no head fixation is required, large volume shifts can be easily accounted for with serial imaging, and the spatial resolution approaches that obtained with extraoperative diagnostic imaging.¹⁴⁰

Closure of the craniotomy defect in the very young child must take into account the continuance of the rapid phase of cranial vault expansion through infancy. Craniotomy flap repair must both ensure cerebral protection and avoid deformity; resorb-

able plating systems that offer secure bony reconstruction while providing plasticity (and avoiding the phenomenon of intracranial "displacement" of metallic hardware during the process of outward calvarial remodeling) have become the preferred mode toward these ends. Commercially available resorbable plating systems utilizing polyesters of lactic acid (polylactic acid, or PLA) and glycolic acid (polyglycolic acid, or PGA) have been widely studied in the craniofacial literature. PLA derivatives have intrinsic strength and durability related to their hydrophobic and crystalline properties, but these qualities may also make them more likely to cause foreign body reactions. PGA polyesters are more absorbable, but they have less tensile strength. Modern plating systems are copolymers and afford the benefits of both.¹⁴¹⁻¹⁴⁵

33.14.3 Adjuvant Therapy

The conventional approach of postoperative radiation therapy with or without chemotherapy in the treatment of malignant primary brain tumors in infants and very young children has been unsatisfactory.^{52,146,147} The use of cranial irradiation in children younger than 3 years is associated with an unacceptable rate of adverse late effects, including growth failure, mental retardation, leukoencephalopathy, and secondary cancers.^{61,148-157} Thus, various therapeutic strategies have been explored in an effort not only to increase survival rates but also, just as importantly, to improve the quality of life of survivors. Some of these therapeutic approaches are outlined below.

Neoadjuvant Chemotherapy

The unacceptably high incidence of adverse sequelae in young children after conventional craniospinal radiation therapy has been the primary impetus for the development of alternative therapeutic strategies. One such approach has employed the concept of postoperative chemotherapy with the intent to either eliminate or delay the use of irradiation. At MD Anderson Cancer Center, children younger than 36 months who had brain tumors received chemotherapy without radiation therapy, with a 5-year PFS rate of 55% for children with medulloblastoma.¹⁵⁸ The POG in 1993 reported on the results of a larger cooperative study in which postoperative chemotherapy was used with the intent of delaying radiation therapy for 1 to 2 years following surgery.⁵² In that study of nearly 200 children younger than 3 years at the time of study entry, the PFS rate was 41% at 1 year for children ages 24 to 36 months and 39% at 2 years for those younger than 24 months at diagnosis. Embryonal tumors indicated a poorer outcome, whereas complete surgical removal was a positive predictive feature. Most recurrences were observed early at the primary site. Similarly, the CCG reported on their results with an approach in which neoadjuvant chemotherapy and delayed involved field or craniospinal radiation therapy were used in children younger than 18 months at diagnosis.⁴³ That group reported 3-year PFS rates of 22% and 26% for children with medulloblastoma and ependymoma, respectively. Overall, that rate was significantly dependent on the presence or absence of metastatic disease (11% compared with 29%).

A primary chemotherapy approach has been used in an attempt to avoid cranial irradiation and many of the adverse neuroendocrine and neurodevelopmental sequelae that are nearly ubiquitous with radiation therapy in infancy.⁵¹ Pre-irradiation chemotherapy results in a higher radiographic response rate in children younger than 36 months than in older children (33% vs. 11%).¹⁵⁹ In summary, improvements in objective response rates and disease-free intervals, although not lasting, are accomplished with some regularity with the use of neoadjuvant chemotherapy before irradiation in very young children. Furthermore, the detrimental sequelae of immediate postoperative radiation therapy do appear to be attenuated with such an approach.

However, it has been found on longer follow-up analysis that disease recurrence is somewhat influenced by the duration of chemotherapy. Infants treated with chemotherapy for longer than 12 months were found to have a greater likelihood of experiencing disease recurrence than were children receiving 12 months or less of chemotherapy followed by irradiation.^{12,160} This divergence in outcome is attributed to a longer delay in offering radiation therapy.

Some evidence indicates that although the treatment design of delayed radiation therapy and neoadjuvant chemotherapy in infants may reduce radiation-induced neurotoxicity, this reduction may be at the expense of second malignancies. In 1997, it was reported that the original cohort of patients treated with the POG protocol had an 11% risk for a second malignancy within 8 years of treatment.¹² This risk was even higher (19%) for children in whom therapy was initiated before the age of 2 years. It was speculated that alkylating agents and topoisomerase inhibitors were the most probable causes, although 2 of 5 patients with secondary malignancies did receive delayed irradiation. The results of such studies are difficult to interpret with respect to causation because an equally likely hypothesis suggests that survivors of childhood cancer probably have a genetic predisposition to oncogenesis.¹⁶¹

Dose-Intensified or High-Dose Chemotherapy

The promising results of using chemotherapy in an effort to delay or avoid radiation therapy in young children, especially as it relates to the reduction of long-term sequelae, has been the basis behind attempts to optimize chemotherapeutic effects on disease control. The intensification of chemotherapeutic regimens has proved to be beneficial in children with various cancers, including neuroblastoma, osteosarcoma, and leukemia. In 1991, a similar approach of dose intensification was undertaken for young children with CNS malignancies (“Head Start”).⁶¹ This approach used intensive neoadjuvant chemotherapy followed by myeloablative chemotherapy and autologous bone marrow rescue in patients who exhibited a radiographic complete response. Radiation therapy was reserved for patients with residual or recurrent disease after therapy. In that particular study, which included patients younger than 72 months of age at the time of treatment, 40% were free of disease progression at a median of greater than 44 months after treatment. Furthermore, neuropsychological examination revealed that cognitive function was preserved in those patients who avoided radiation therapy.¹⁶² This approach has been subsequently used in Head

Start II in patients with disseminated medulloblastoma.¹⁶³ A group of 21 patients with a mean age of 38 months were treated with intensified chemotherapy with autologous stem cell rescue. Patients younger than 6 years of age who had no evidence of disease after chemotherapy did not receive radiation therapy. The 3-year EFS and OS rates were 49% and 60%, respectively. Wide acceptance of this therapeutic approach is somewhat tempered by a toxic mortality rate between 5% and 8%. Whether similarly admirable results are achievable in children younger than 3 years is currently unknown, but the control rates and the improved neuropsychological outcome in children avoiding radiation therapy suggest that this treatment regimen is encouraging for the very young child with a malignant brain tumor.

Preoperative Chemotherapy and Second-Look Surgery

The relatively large tumor size in conjunction with the frequent hypervascularity of many primary brain tumors in infants, as outlined previously, can limit the ability to obtain radical resection safely. For a variety of tumors, a therapeutic strategy of administering preoperative neoadjuvant chemotherapy facilitates aggressive surgical therapy. This approach results in a dual benefit by decreasing the overall size and diminishing the hemorrhagic potential of malignant brain tumors in infants. This therapeutic strategy has been shown to positively influence the treatment of young children with choroid plexus carcinoma^{97,99,100} and PNET.^{97,164}

Benefit has been realized not only with preoperative chemotherapy but also with chemotherapy between treatment regimens. The result is similar in that definitive removal of tumors appears to be enhanced and safer. This approach, termed second-look surgery, has been applied successfully in children with ependymoma, germ cell tumors, and various malignant hypervascular tumors.^{75,165-167} An improved extent of surgical removal been purported, and in addition, second-look surgery has been integrated into treatment protocols before consolidation chemotherapy.¹⁶³ With such an approach, only those children with no evidence of radiographic disease before consolidation chemotherapy had improved outcomes. One recent report of the St. Jude Children’s Research Hospital experience in which neoadjuvant chemotherapy was used before second-look surgery describes radiographic response in 9 of 13 and the achievement of gross total resection in 11 of 13 infants with a variety of pathologies. Two patients required emergency surgery for complications of chemotherapy, including intratumoral hemorrhage and peritumoral edema.¹⁶⁸

Focused Radiation Therapy

Numerous studies have shown a convincing relationship between the use of radiation therapy and the significant late effects experienced by survivors of childhood brain tumors. These untoward effects principally include endocrine abnormalities, impaired axial growth, hearing impairment, neuropsychological dysfunction, and secondary tumors.^{61,148-156} With particular emphasis on the treatment of very young children, an inverse relationship exists between the age at which radiation therapy

is used and the frequency and severity of late effects. Adverse sequelae are found even when low-dose or reduced-dose radiation therapy has been employed.^{157,169} As a result, the liberal use of craniospinal or whole-brain irradiation has been nearly abandoned in treatment approaches for children younger than 3 years. This tenet obviously has had a profound effect upon disease-free intervals in children with many of the primary tumors of infancy, particularly the highly radiosensitive neuroepithelial tumors.

However, recent refinements in focused radiation therapy have brought about a renewal of interest in the potential use of irradiation for very young children. Millimeter scaling in prescribed dosing, reproducible stereotactic localization in children, triplanar imaging with three-dimensional targeting, and inverse dose planning have resulted in the development of highly conformal radiation therapy. This form of radiation therapy is administered through a variety of means, including three-dimensional conformal radiation therapy, stereotactic radiation therapy, intensity-modulated radiation therapy, and proton beam radiation therapy. With the use of conformal fields, the prescribed dose is localized to the tumor, thereby reducing radiation to the surrounding normal brain. Conformal radiation therapy thus offers the possibility of reducing the long-term adverse effects of irradiation and may be applicable in very young children.

Early clinical data indicate that control rates for both benign and malignant tumors of childhood are at least comparable if not better than those achieved with conventional radiation fields.¹⁷⁰⁻¹⁷⁶ With the use of either three-dimensional conformal radiation therapy or intensity-modulated radiation therapy in children with medulloblastoma, limited clinical trials have shown a 65% reduction in exposure of the cochlea to radiation in comparison with exposure when conventional planning was used.^{177,178} This planned reduction in exposure of the cochlea to radiation has been realized in clinical trials of patients with medulloblastoma.¹⁷⁹ These approaches have also shown an 86% local control rate at 10 years in children with medulloblastoma.¹⁸⁰

The application of conformal radiation therapy in infants with intracranial neoplasms has thus far been limited. A report on 88 children with ependymoma treated with three-dimensional conformal radiation therapy at St. Jude Children's Research Hospital has been published.⁷³ The median age of that cohort of patients was 4.5 years, with 15 children younger than 18 months at the time of treatment. The 3-year PFS rate was 75% at a mean follow-up of 38 months. The cumulative local failure rate was 15%, and mean scores on neurocognitive testing were within normal limits at a minimum of 24 months. These encouraging results have led to the integration of conformal radiation therapy as an adjunct for infants in future cooperative group trials.

Although the avoidance of critical normal structures and control rates are achieved with these highly conformal irradiation schemes, concerns about radiation-induced cancer and radiation necrosis have been raised.^{174,178} Altering the energy source through the use of photons is theoretically advantageous with respect to secondary tumors, but longer follow-up will be required before firm conclusions can be drawn about these potential adverse effects.¹⁸¹

Intrathecal Chemotherapy

The prophylaxis and treatment of leptomeningeal dissemination in very young children remain problematic, given the known detrimental effects of craniospinal irradiation in this population of patients. Intrathecal chemotherapy, although logical as a modality of therapy for disseminated or potentially disseminated embryonal tumors, has been limited by technical issues pertaining to therapeutic administration and the limited number of safe intrathecal agents. Because of the widespread use and good safety record of intrathecal methotrexate and cytarabine for children with CNS leukemias or lymphomas, these agents have logically been used most extensively for the treatment of leptomeningeal dissemination of primary brain tumors.

The experience with 62 children with medulloblastoma who were younger than 3 years at the time of treatment was recently reported.⁴² As part of the treatment approach, all children received intrathecal methotrexate as an alternative to craniospinal irradiation. The respective 5-year PFS and OS rates were 82% and 93% for patients who had complete tumor resection, 50% and 56% for patients who had residual tumor, and 33% and 38% for children with macroscopic evidence of disease. Although radiographic leukoencephalopathy was found in nearly half of all patients, no patients exhibited symptoms. Furthermore, a cognitive assessment revealed a reduction in function in comparison with aged-matched controls but better function in comparison with historical controls treated with craniospinal irradiation. It thus appears from this particular study that intrathecal prophylaxis against leptomeningeal disease can be achieved and causes fewer detrimental effects than conventional craniospinal irradiation in very young children.

Encouraging results have also been shown in several patients with highly malignant AT/RTs when an intensive chemotherapeutic approach incorporating intrathecal methotrexate and cytarabine was used.^{113-115,182} The use of intrathecal multiple-agent chemotherapy in most cases was supplemented with focused radiation therapy or craniospinal irradiation. However, given the typical very poor prognosis of children with AT/RT, these results are encouraging and lend further support for adding an intrathecal component to the regimen for leptomeningeal treatment or prophylaxis in young children.

The conceptual issues regarding intrathecal therapy are apparent, and the use of intrathecal methotrexate and cytarabine has further substantiated this approach. Attention has recently been directed to the intrathecal administration of other agents that have proved useful against embryonal brain tumors when administered systemically. Notably, the Pediatric Brain Tumor Consortium has recently investigated in a pilot study the use of intrathecal mafosfamide, a preactivated derivative of the alkylating agent cyclophosphamide, in combination with systemic chemotherapy, conformal radiation, and second-look surgery.¹⁸³ The study established the feasibility of this regimen in 71 children ages 3 years or younger with embryonal tumors; although it appeared to deliver outcomes similar to those in historical controls, this work will likely serve as the basis for future clinical trials specifically designed to evaluate efficacy.

Pearls

- Brain tumors of infancy are commonly composed of histologic subtypes (atypical teratoid rhabdoid tumor, choroid plexus carcinoma, desmoplastic tumors of infancy, pilomyxoid astrocytoma) that are rare in older children and adults.
- Infantile brain tumors are frequently voluminous and located in the supratentorial compartment.
- Surgical mortality in this population is most commonly attributed to blood loss, and appropriate preparations for transfusions are mandatory before surgery is begun.
- Pin fixation should be avoided in infants younger than 2 years in an effort to prevent skull fracture or perforation.
- Second-look surgery after neoadjuvant chemotherapy is an evolving and effective surgical strategy for infants with large malignant tumors.

34 Supratentorial Hemispheric Gliomas

Ian F. Pollack

The majority of supratentorial hemispheric tumors in children are gliomas,¹ which is similar to the situation in adults. However, a distinguishing feature is the histologic distribution of these tumors; whereas malignant gliomas account for the bulk of intraparenchymal lesions in adults, low-grade gliomas account for the overwhelming majority of such tumors in children. In addition, meningiomas, which are among the most common supratentorial tumors in adults, are rare in children. Another important characteristic of pediatric hemispheric tumors is the strong association between the extent of tumor resection and outcome for virtually all tumor types, including malignant lesions, which may reflect age-related features in the biological behavior of these neoplasms. The present chapter focuses on supratentorial hemispheric gliomas and reviews the epidemiology, pathology and molecular pathogenesis, clinical presentation, diagnostic evaluation, treatment, and outcome of these tumors. In addition, it presents recent advances in intraoperative localization and mapping techniques that have allowed extensive surgical cytoreduction to be achieved with greater safety and reliability.

34.1 Epidemiology

Low-grade gliomas account for almost 60% of supratentorial hemispheric tumors in children and occur at an incidence of approximately 5 cases per 1 million children a year.^{1,2} More than half of such lesions are low-grade astrocytomas. The remainder are mixed gliomas, oligodendrogliomas, gangliogliomas, and a host of less common lesions, such as pleomorphic xanthoastrocytomas,³ dysembryoplastic neuroepithelial tumors,⁴ and desmoplastic infantile gangliogliomas,⁵ which occur most commonly in the pediatric age group. High-grade gliomas comprise approximately 20% of hemispheric lesions.¹

Although a definite environmental or genetic cause for most gliomas is unknown, a subgroup of affected children do have an underlying genetic syndrome, such as type 1 neurofibromatosis (NF1), tuberous sclerosis, or Turcot syndrome, that predisposes them to the development of central nervous system (CNS) tumors. NF1 (discussed in greater detail in Chapter 48) is caused by a mutation in the neurofibromin gene on chromosome 17q11.2,⁶ which encodes a protein with guanosine triphosphatase-activating properties that functions in signal transduction. Although the most characteristic intracranial neoplasms in affected patients are optic pathway gliomas, lesions develop in the cerebral hemispheres in a small percentage of patients. These are generally low-grade gliomas⁷; however, high-grade lesions have also been observed.

Patients with tuberous sclerosis commonly have seizures, mental retardation, and adenoma sebaceum in addition to cortical and subependymal hamartomas (tubers), angioliomyomas of the kidney, rhabdomyomas of the heart, and subependymal giant cell astrocytomas arising in the region of the foramen of Monro. This syndrome has been linked to mutations in the *TSC1* or *TSC2* genes, which drive tumor growth via the mammalian target of rapamycin (mTOR) signaling pathway.^{8,9}

Patients with Turcot syndrome exhibit multiple colonic polyps in association with intracranial neoplasms. This disorder results from mutations in the adenomatous polyposis coli (*APC*) gene and in DNA mismatch repair genes.¹⁰ Affected patients generally have malignant gliomas or primitive neuroectodermal tumors (PNETs). Several less common syndromes have also been linked anecdotally with glial neoplasms.

34.2 Pathology

Cerebral hemispheric low-grade gliomas are generally subdivided into several major groups, based on their presumed cell of origin.^{11,12} These groups include (1) astrocytic tumors, including pilocytic and nonpilocytic astrocytoma, pleomorphic xanthoastrocytoma, and subependymal giant cell astrocytoma; (2) oligodendroglial tumors; (3) mixed gliomas; and (4) benign neuroepithelial tumors, such as ganglioglioma, desmoplastic infantile ganglioglioma, and dysembryoplastic neuroepithelial tumor. Malignant gliomas are subdivided into anaplastic astrocytoma, mixed glioma or oligodendroglioma (grade III), and glioblastoma (grade IV). The appearances of the most common histologic subgroups of gliomas are illustrated in ► Fig. 34.1.

Daumas-Duport et al¹³ proposed a relatively simple grading system for nonpilocytic astrocytomas based on a limited number of histologic features. Lesions were given one point for each of the following factors: nuclear atypia, mitoses, endothelial proliferation, and necrosis. Grade 1 lesions had none of these characteristics, grade 2 had one, grade 3 had two, and grade 4 had three or four. Because these criteria generally appeared in sequence, grade 2 tumors were generally characterized by nuclear atypia, grade 3 by their mitotic activity, and grade 4 by the presence of either necrosis or endothelial proliferation. A modified version of this simplified scheme has been incorporated into recent World Health Organization (WHO) classification guidelines.¹²

Pilocytic astrocytomas are characterized by areas of compact bipolar astrocytes alternating with loosely packed areas containing microcysts. Macrocysts are also common. Eosinophilic granular bodies and Rosenthal fibers are characteristically seen. Occasional mitotic figures, leptomeningeal infiltration, and vascular proliferation do not appear to affect prognosis adversely, in contrast to the situation with nonpilocytic astrocytomas.

Pleomorphic xanthoastrocytomas arise most commonly in the temporal or parietal lobes and are often associated with a cyst. These lesions are characterized by pronounced nuclear atypia with pleomorphism and multinucleation in the setting of a low mitotic index. Abundant lipid-rich cells and pronounced reticulin reactivity, particularly in the regions of leptomeningeal invasion, are also typical. Approximately 20% of these lesions undergo malignant transformation, with pronounced mitosis, necrosis, and endothelial proliferation.^{3,12}

Subependymal giant cell astrocytomas arise near the foramen of Monro and contain large cells resembling astrocytes. Perivascular pseudopalisading is often seen, but mitoses are rare. Immunoreactivity for both glial and neuronal markers is often noted.

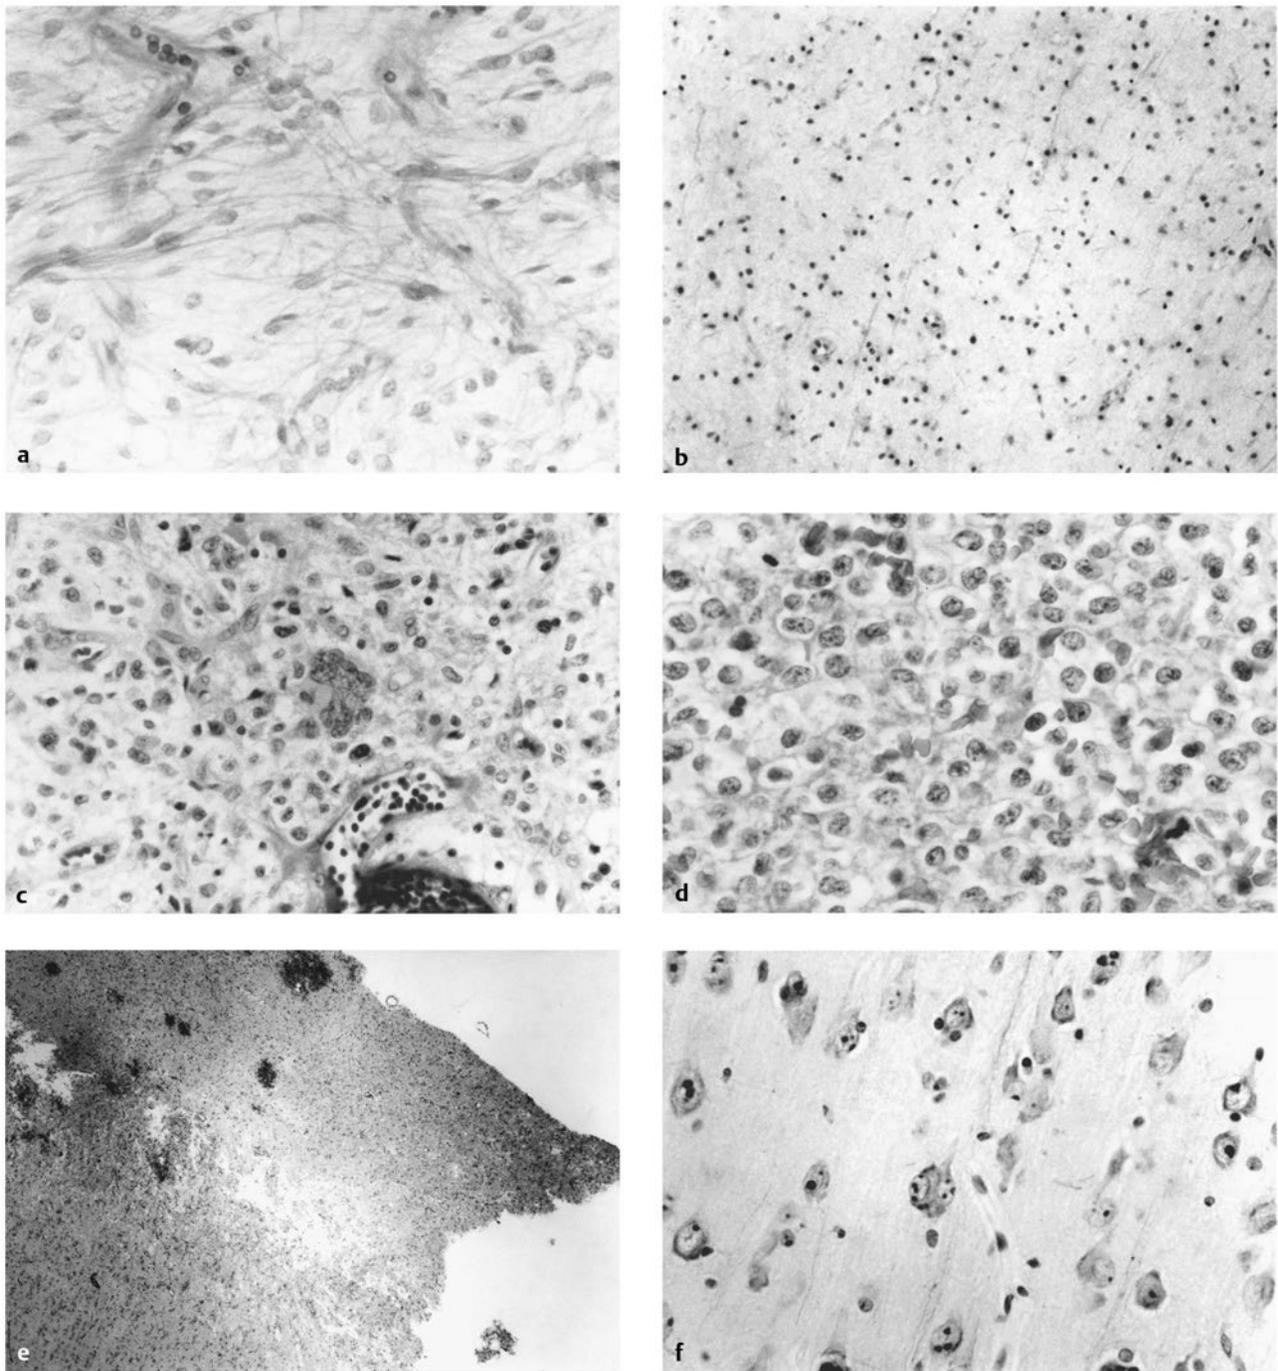

Fig. 34.1 Histologic appearance of common supratentorial hemispheric gliomas. (a) Pilocytic astrocytoma (hematoxylin and eosin [H&E]). Typical piloid (hairlike) processes with abundant Rosenthal fibers are apparent. (b) Nonpilocytic astrocytoma (H&E). This lesion exhibits monotonous sheets of minimally atypical neoplastic astrocytes, without mitosis or necrosis. (c) Malignant glioma (H&E). This specimen exhibits mitosis, necrosis, and vascular proliferation, all hallmarks of a glioblastoma multiforme. (d) Oligodendroglioma (H&E). The tumor is composed of cells that exhibit a characteristic “fried egg” appearance. (e) Mixed oligoastrocytoma (H&E). In this specimen, discrete foci of astrocytoma and oligodendroglioma are apparent, although in many lesions, the separation of such cell populations is less obvious. (f) Ganglioglioma (Nissl stain). Binucleated neoplastic neurons in a background of neoplastic astrocytes are illustrated.

Oligodendroglial tumors are characterized by spherical cells with hyperchromatic nuclei and a well-defined plasma membrane that gives a “fried egg” appearance. Focal calcifications are common. Lesions that exhibit a major astrocytic component, either diffusely or in distinct regions, are classi-

fied as mixed gliomas. Both oligodendrogliomas and oligoastrocytomas can exhibit features of anaplasia, with mitoses, necrosis, and vascular proliferation that, in some cases, may be difficult to distinguish from the features of glioblastoma multiforme.

Each of the benign neuroepithelial tumors has distinctive morphological characteristics. Gangliogliomas are characterized by the presence of neoplastic neurons with binucleation and atypia in a background of neoplastic astrocytes.¹⁴ Desmoplastic infantile ganglioglioma is notable for the young age of affected patients, the large size of the lesion, and the presence of a pronounced desmoplastic component containing a mixture of cells with astrocytic and neuronal differentiation.¹⁵ Finally, dysembryoplastic neuroepithelial tumor is notable for a cortical location, multinodular architecture containing neoplastic oligodendrocytes, neurons, and astrocytes, and an internodular neuroglial component, with neurons in a background of oligodendroglial cells.⁴

34.3 Molecular Pathogenesis

Recent studies have provided major insights into the molecular basis for pilocytic astrocytomas. A significant percentage of these tumors have alterations in the *BRAF* gene, either activating mutations, such as *BRAF* V600E, or translocations that produce a constitutively active variant, which leads to dysregulated signaling via the mitogen-activated protein kinase (MAPK) pathway.^{16–19} Similarly, dysregulation of mTOR signaling has been found to underlie the development of subependymal giant cell astrocytomas in tuberous sclerosis.^{8,9} In both cases, these consistent molecular alterations have provided a basis for logical strategies for molecularly targeted therapy. Studies of other pediatric gliomas have failed to demonstrate a consistent pattern of genetic abnormalities. Although adult low-grade gliomas frequently evolve secondarily into higher-grade lesions,^{20–23} this stepwise progression is less frequent in childhood gliomas, suggesting that there are fundamental differences between these groups. Adult grade II astrocytomas and the secondary malignant gliomas that arise from them commonly exhibit mutations in the *IDH1* or *IDH2* gene,^{22–24} whereas such mutations are uncommon in childhood lesions, with the exception of those arising in adolescence.²⁵ Likewise, adult lesions commonly have mutations in *TP53*; although these are found in a subset of childhood malignant gliomas, such mutations are rare in low-grade gliomas.²⁶ Childhood lesions are different from primary adult malignant gliomas, which are grade IV lesions at diagnosis; adult lesions characteristically exhibit deletions or mutations of the *PTEN* gene in association with amplification and/or rearrangement of the *EGFR* gene,^{23,27} whereas such abnormalities are observed in fewer than 10% of pediatric lesions.²⁸ However, recent studies indicate that a subset of pediatric malignant gliomas have amplification of the *PDGFRA* gene, or alterations of the *H3F3A* or *ATRX/DAXX* genes, suggesting that these tumors may have alternate pathways to gliomagenesis and thus may warrant distinctive therapeutic approaches.^{29,30,106}

One consistent finding in both childhood and adult malignant gliomas is the adverse association between overexpression of the DNA repair protein methylguanine-DNA methyltransferase (MGMT) and response to alkylating agents.^{31–33} Children treated with nitrosourea- or temozolomide-based regimens whose tumors have a low level of MGMT expression have a significantly better prognosis than those whose tumors show MGMT overexpression.^{32,33}

34.4 Clinical Presentation

Cerebral hemispheric gliomas characteristically present with seizures and focal neurologic deficits, such as hemiparesis, hemisensory deficits, and aphasia, depending on the site of the lesion and the age of the child (see box “Signs and Symptoms of Cerebral Hemispheric Gliomas”).³⁴ Whereas low-grade lesions often present with an insidious onset of symptoms over a period of months or with a long history of seizures, the mode of symptom progression in high-grade lesions is generally more rapid. Signs of increased intracranial pressure (ICP) and focal neurologic deficits are seen more commonly with high-grade lesions than with low-grade lesions. A small percentage of children present with sudden neurologic deterioration, which in most cases reflects intratumoral hemorrhage.

Signs and Symptoms of Cerebral Hemispheric Gliomas

- Common signs and symptoms
 - Seizures
 - Hemiparesis
 - Hemisensory deficits
 - Aphasia/dysphasia
 - Headaches
- Uncommon signs and symptoms
 - Vomiting
 - Macrocephaly
 - Failure to thrive
 - Papilledema
 - Lethargy

The characteristic mode of presentation for benign neuroepithelial tumors, such as ganglioglioma and dysembryoplastic neuroepithelial tumor, is with partial complex seizures that in many cases are refractory to anticonvulsant medications. Signs of increased ICP and focal neurologic deficits are infrequent. In many cases, seizures have been present for years before the diagnosis. However, desmoplastic infantile ganglioglioma is a notable exception to this general pattern. Because these tumors often arise during infancy and are large, affected patients commonly present with the gradual onset of macrocephaly and other signs of increased ICP, such as a bulging fontanel, “setting sun” eye sign, and failure to thrive.

In the past, subependymal giant cell astrocytomas characteristically manifested with symptoms of increased ICP secondary to ventricular dilatation from obstruction of the foramen of Monro or with seizures and hemiparesis from involvement of the overlying frontal cortex. With the widespread availability of high-resolution imaging techniques, such tumors are now often detected at a presymptomatic stage on screening neuroimaging evaluations of children with tuberous sclerosis.

34.5 Diagnostic Studies

Computed tomography (CT) or preferably magnetic resonance (MR) imaging is usually the only diagnostic study needed to establish the presence of a supratentorial hemispheric tumor (► Fig. 34.2). Low-grade astrocytomas are typically hypodense

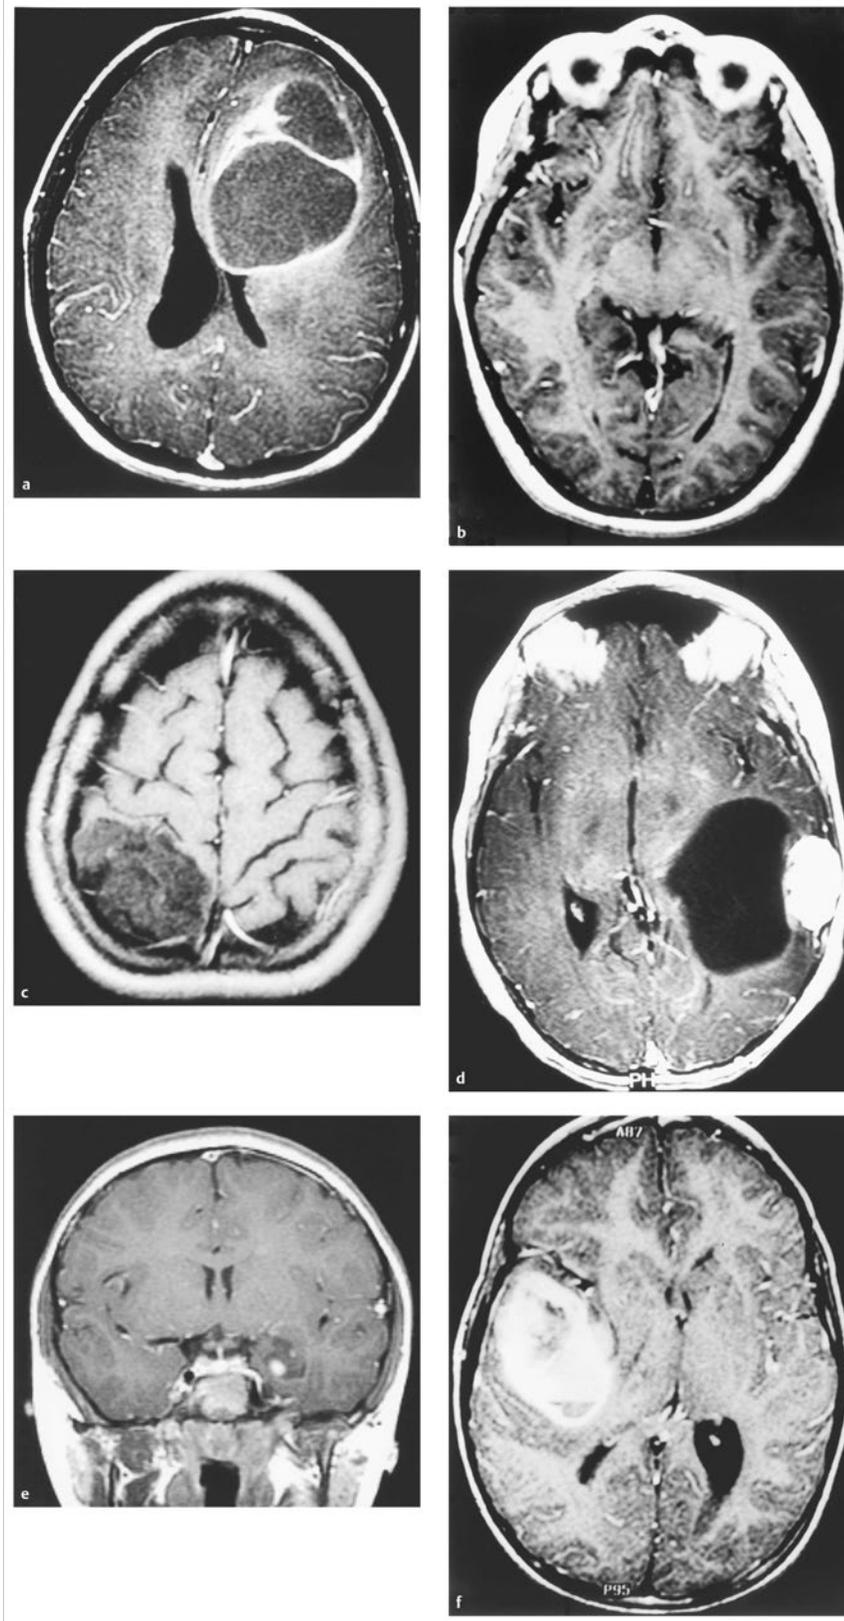

Fig. 34.2 Magnetic resonance images of common supratentorial hemispheric gliomas. (a) Pilocytic astrocytoma. (b) Nonpilocytic astrocytoma. (c) Oligodendroglioma. (d) Pleomorphic xanthoastrocytoma. (e) Dysembryoplastic neuroepithelial tumor. (f) Malignant glioma.

on a CT scan and hypointense on a T1-weighted MR image in comparison with the surrounding brain. Pilocytic tumors often exhibit well-defined borders with enhancement in the form of a mural nodule. However, a uniform or ringlike pattern of

enhancement is sometimes observed. In contrast, nonpilocytic tumors are often poorly delimited on a CT scan or T1-weighted MR image and appear as a poorly circumscribed area of increased signal on T2-weighted images. These lesions often show

little or no enhancement, but some cases closely resemble pilocytic tumors. Oligodendrogliomas and gangliogliomas may resemble either pilocytic or nonpilocytic astrocytomas but are more likely to show calcification; of the two, gangliogliomas are more likely to arise in the temporal lobe.

Pleomorphic xanthoastrocytomas characteristically arise at or close to the cortical surface in association with an underlying cyst. Enhancement of the solid tumor component is typically seen. Subependymal giant cell astrocytomas appear as well-circumscribed, homogeneously enhancing lesions located adjacent to the foramen of Monro and are often associated with obstructive hydrocephalus. Desmoplastic infantile gangliogliomas are characterized by their superficial location, which often extends to the leptomeninges, and their large size. These lesions are often partially cystic and have a densely enhancing solid component. Dysembryoplastic neuroepithelial tumors appear as well-demarcated, superficial lesions that are hypodense on CT and hypointense on T1-weighted MR imaging, giving a pseudocystic appearance. Enhancement, if present, is slight.

Malignant gliomas typically exhibit irregular or ringlike enhancement on CT and MR imaging, with a surrounding area of low density on CT, low intensity on T1-weighted MR imaging, and high intensity on T2-weighted MR imaging that represents infiltrating tumor and edema. Because these lesions grow more rapidly than low-grade gliomas, they often produce a substantially greater local mass effect. It is sometimes difficult to distinguish these lesions from other malignant hemispheric tumors, such as ependymomas and PNETs.

Other diagnostic studies are rarely needed preoperatively. Lumbar puncture should specifically be avoided because of the risk for herniation in the setting of a large mass lesion. Angiography is indicated only if a tumor exhibits unusual vascularity, in which case preoperative embolization may be considered, or if concern is raised that the lesion may be a vascular malformation. Neuraxis imaging is needed for only a subset of supratentorial tumors, such as PNETs, and unless this diagnosis is strongly suspected, it is typically reserved for the postoperative period after a histologic diagnosis has been obtained.

34.6 Surgical Treatment

34.6.1 Perioperative Management

Most children referred for neurosurgical evaluation have already had an adequate-quality MR imaging examination that is sufficient for operative planning. However, an additional imaging study suitable for intraoperative neuronavigation is sometimes needed, which helps both to localize the lesion and to assist with operative planning. The timing of operative intervention is largely determined by the condition of the child. Patients who present with obtundation from a large mass undergo resection on the day of admission. Children who have a large lesion but are minimally symptomatic undergo surgery on the next available operating day. Smaller lesions that present with seizures and minimal mass effect are treated on a more elective basis.

Corticosteroids are generally begun on admission in children with large tumors or are administered preoperatively in patients with smaller lesions at a dose in the range of 0.1 mg/kg every 6 hours (for dexamethasone). These are continued

intraoperatively and then tapered during a period of 3 to 7 days if significant tumor debulking has been achieved. Because children with hemispheric tumors may be at risk for seizures during the perioperative period, anticonvulsants are often begun preoperatively, even if the child has not previously had a seizure, and maintained for at least 1 week postoperatively. The use of longer courses of anticonvulsants in patients without a history of seizures is of uncertain benefit. In patients with a history of preoperative seizures, the duration of postoperative anticonvulsants is largely empiric. Many groups discontinue the anticonvulsants several months after surgery if the child has been rendered seizure-free. In view of the trend toward minimizing or avoiding hair shaving for neurosurgical procedures, an antibacterial shampoo on the night before surgery and on the morning of surgery is often employed to decrease skin and hair flora.

Because cerebral hemispheric gliomas rarely produce significant hydrocephalus, external ventricular drainage is normally not initiated preoperatively. In the occasional case in which a ventricle is partially trapped or expanded by tumor and the risk for perioperative hydrocephalus is a concern, a ventricular catheter may be placed intraoperatively and then withdrawn by gradually raising the drainage chamber during the first several days after the tumor resection. Few children require shunts as a part of their initial operative management.

34.6.2 Surgical Planning

In general, surgical intervention forms the initial step in the treatment plan by providing tissue with which to establish the histologic diagnosis and by achieving cytoreduction, if this is safely feasible. An important consideration in selecting the optimal approach to a supratentorial hemispheric lesion centers around developing a clear plan of the goals of the operation (e.g., biopsy, reduction of mass effect, gross total resection, and/or treatment of hydrocephalus), which are influenced by the growth characteristics of the tumor as depicted by CT or, preferably, MR imaging. Ideally, for well-circumscribed lesions, a gross total resection should be the operative goal, if this can be achieved without inordinate risk. This is feasible for most pilocytic astrocytomas, even if they arise in subcortical regions, for many superficial nonpilocytic astrocytomas and benign neuroepithelial tumors, and for some superficial high-grade gliomas. Because there appears to be a major prognostic advantage to obtaining a gross total or nearly total resection of these tumors,³³⁻³⁷ the extra risk involved in achieving this goal may be justified by the potentially improved outcome that can be realized.

Conversely, for some infiltrative, poorly circumscribed high-grade gliomas and nonpilocytic low-grade gliomas that cross the midline or extensively invade the deep nuclei and other critical brain regions, substantial resection may not be feasible without unacceptable morbidity. In small or highly diffuse lesions with minimal local mass effect, a percutaneous image-guided stereotactic biopsy may be preferable to an extensive open operation with limited tumor removal as a means for safely establishing a histologic diagnosis in preparation for adjuvant therapy. However, for large lesions with extensive mass effect and a well-defined "core" on imaging, an open biopsy combined with an aggressive subtotal resection may be of value

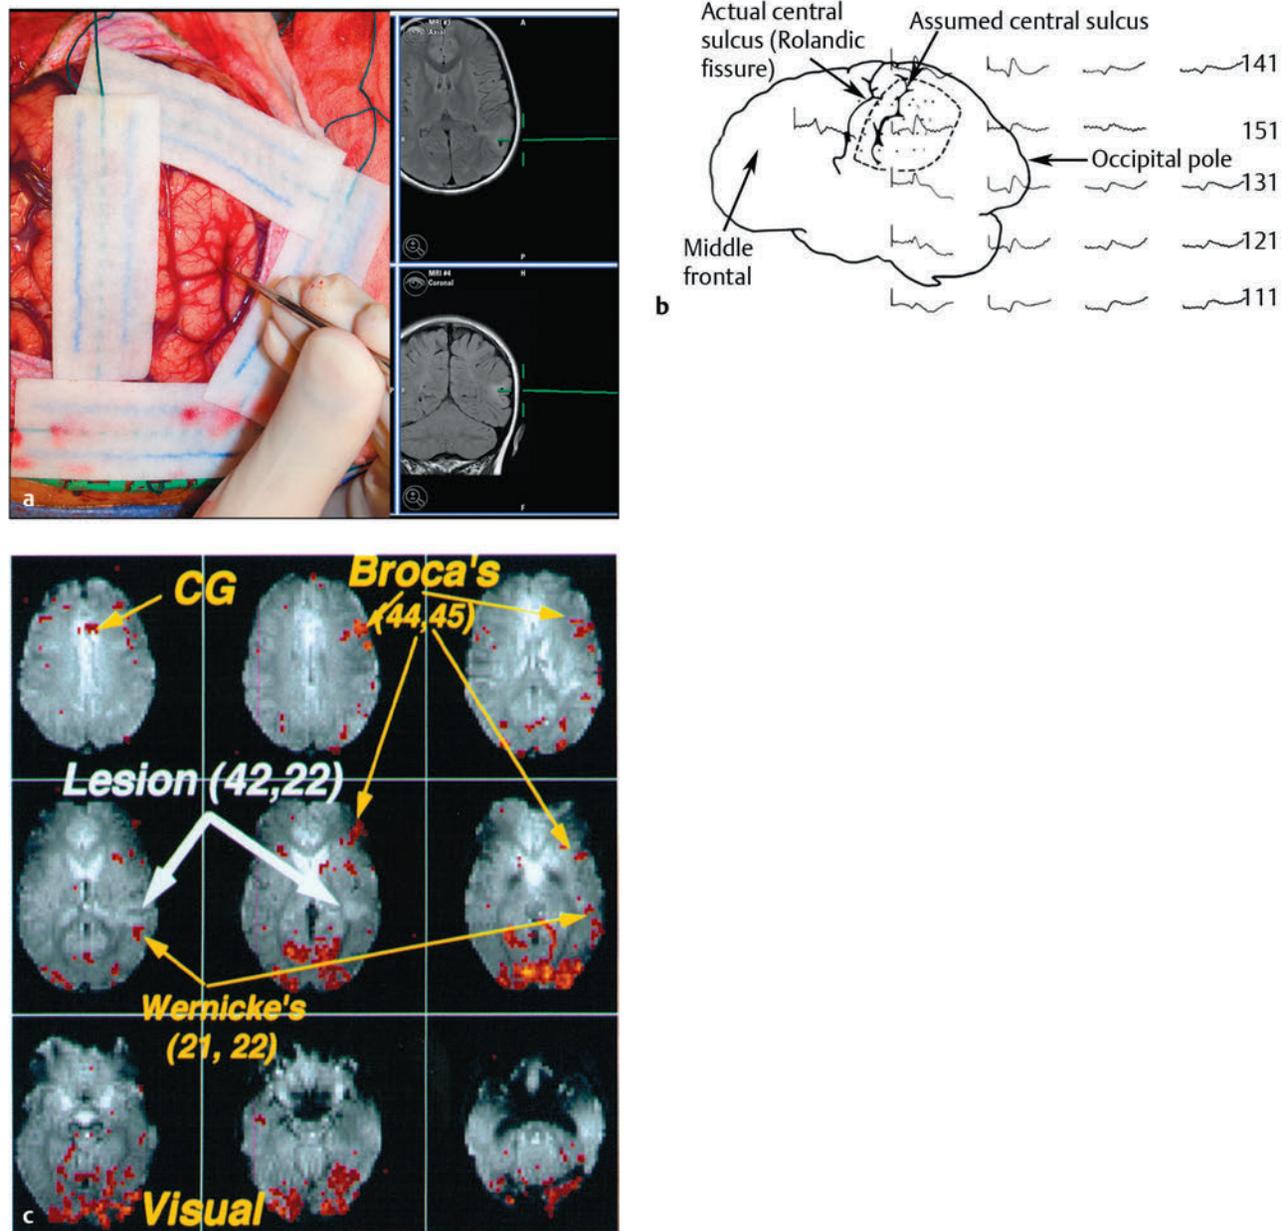

Fig. 34.3 Preoperative and intraoperative adjuncts that facilitate tumor resection. (a) Stereotactic localization with frameless navigation allows planning of the operative trajectory and facilitates anticipation of the tumor margins during the course of the resection. (b) Intraoperative somatosensory evoked potential mapping of the central sulcus, which, as illustrated here, is often displaced or distorted by a nearby tumor. In this case, the data recorded from a strip electrode positioned over the lesion, both posterior and anterior to the presumed central sulcus, all demonstrated a classic N20, P30 complex, suggesting that this region was actually parietal cortex. Only when the recording strip was advanced anterior to the lesion was an N20, P30 inversion consistent with motor cortex observed. (c) Functional magnetic resonance image mapping of speech functions, which, as illustrated here, are in close proximity to a dominant parietal tumor.

in stabilizing the patient in preparation for further treatment. In the latter circumstances, the goal should be to take out as much tumor as possible while minimizing the risk for neural injury.

Fortunately, several adjuncts have become available that facilitate the extensive removal of lesions previously thought to be unresectable, or resectable only with substantial morbidity (► Fig. 34.3). Stereotactic guidance systems allow preoperative and intraoperative localization of the tumor, which permits the

surgeon to choose an operative approach that minimizes the manipulation of functionally critical brain and maximizes the extent of resection that can be achieved (► Fig. 34.3a). Ultrasound and intraoperative MR imaging are also increasingly used to provide real-time feedback on the location of the lesion, which avoids problems with intraoperative brain movements that limit the accuracy of stereotactic techniques after the tumor resection has been initiated. However, particularly for MR imaging, the significant cost of an intraoperative scanner and

the lengthened operative times needed to apply this modality constitute drawbacks to more widespread application.

A variety of techniques have also been developed for the functional localization of critical brain areas in the vicinity of a superficial tumor or overlying a deep-seated lesion. For superficial lesions, these techniques enable the surgeon to resect as much tumor as possible without damaging vital surrounding structures, and for deep lesions, they allow the surgeon to choose a trajectory to the tumor that avoids traversing important loci. Cortical stimulation techniques,³⁸ which may be applied both extraoperatively, by means of grid or strip electrodes that have been implanted at a preliminary procedure, and intraoperatively, at the time of the planned tumor resection, are useful for identifying speech and motor areas. Although motor mapping can be accomplished in patients who are under general anesthesia, intraoperative speech mapping requires the patient to be awake, which generally limits the applicability of this technique to children older than 10 years. Accordingly, for younger patients, extraoperative mapping is preferable. Intraoperative somatosensory evoked potential recordings (► Fig. 34.3b) are also helpful for delineating the primary sensory cortex and central sulcus in an anesthetized patient, but in contrast to direct stimulation techniques, they are not useful for mapping subcortical pathways. Functional MR (fMR) imaging and diffusion tensor imaging offer alternative approaches for localizing critical cortical and subcortical areas and pathways before a tumor resection is begun (► Fig. 34.3c).^{39,40} This information can be integrated with stereotactic techniques to precisely delineate relevant loci around the tumor. Finally, in patients who have intractable seizures in association with cerebral cortical lesions, electrocorticography provides an opportunity for determining whether or not the seizures originate from the site of the lesion and for identifying epileptogenic cortex adjacent to or distant from the tumor to optimize the chances for postoperative seizure control.³⁸

34.6.3 Anesthesia, Positioning, and Surgical Approaches and Techniques

For hemispheric tumors that are appropriate candidates for open resection, the anesthetic technique, positioning, and surgical approach are determined by the location of the lesion and type of monitoring that is planned. The anesthetic technique generally consists of a mixture of fentanyl, vecuronium, nitrous oxide, and isoflurane. The approach is modified depending on the type of monitoring employed. For example, somatosensory evoked potential monitoring requires a reduction in the levels of inhalation agents, whereas motor mapping requires a limitation in the level of paralysis; the other agents are adjusted accordingly. Achieving reliable monitoring while keeping the patient appropriately anesthetized requires that the anesthesiologist be informed preoperatively of the surgeon's plans. Other common features of the surgical preparation include insertion of a urinary drainage catheter, arterial line, and, if significant blood loss is anticipated, a central line and sizeable peripheral intravenous lines. Prophylactic antibiotics are administered during the skin preparation and periodically during the procedure. Corticosteroids and anticonvulsants are also continued intraoperatively.

The positioning used for tumor resection is commonly supine or lateral decubitus, depending on the operative trajectory. A head fixation device is generally used for children older than 2 to 3 years, whereas a horseshoe headrest is commonly employed in younger patients. We currently avoid shaving large areas of the head; instead, we trim a 1- to 2-cm strip along the planned incision line and then scrub the hair and scalp with an antibacterial soap before a formal skin preparation.

For superficial cortical tumors and subcortical lesions that are not immediately beneath functionally essential cortex, the most direct trajectory to the lesion is usually appropriate (► Fig. 34.4). However, for subcortical lesions that are beneath critical brain regions, stereotactic and/or functional mapping techniques, such as fMR imaging and diffusion tensor imaging, coupled with direct mapping, are useful for selecting the safest approach to the tumor. These strategies are particularly valuable for lesions that arise from or extend into the thalamus and basal ganglia. The approach to these deep subcortical lesions is also influenced by the predominant direction of tumor growth. Lesions that grow medially and encroach on or expand within the lateral ventricle can be approached transcally or transfrontally, whereas tumors that extend laterally in the nondominant hemisphere may be approached through the insula after the sylvian fissure has been opened. Laterally extending lesions within the dominant hemisphere and tumors that arise more posteriorly within the thalamus may be reached via a posterior parietal approach situated behind the sensorimotor cortex and above the angular gyrus. Selected lesions can also be reached via an occipital trajectory. Finally, tumors that project anterolaterally can be reached from a paramedian frontal trajectory, provided that care is taken to avoid injury to the motor pathways.

The skin incision is determined by the location of the lesion, with a question mark, C-shaped, or linear incision for temporal lesions; a bicoronal incision for low frontal lesions; and a linear or C-shaped incision for posterior frontal, parietal, or occipital lesions (► Fig. 34.4). The bone removal and dural opening are performed in a standard fashion.

In most cases, we obtain a frozen section diagnosis after the tumor has been exposed because this information sometimes influences subsequent intraoperative management. For example, for certain diagnoses, particularly ependymoma, the extent of resection has such an overwhelming impact on the prognosis that we are more willing to risk causing a minor neurologic deficit if it will permit a complete resection. Conversely, for a diagnosis of malignant glioma, in which a truly complete resection is not feasible because of the inherent invasiveness of the tumor, we also make a concerted effort to remove the central tumor mass, but we would not "chase" the lesion into surrounding infiltrated brain tissue.

The actual tumor resection is usually initiated with the use of ultrasonic aspiration to debulk the center of the lesion. Some low-grade gliomas, particularly pilocytic tumors, have a well-delineated peritumoral plane through which the neoplasm can be separated from the surrounding brain after the central portion of the mass has been debulked. With most nonpilocytic gliomas and high-grade gliomas, no such plane is observed, and the resection must proceed cautiously from the inside outward until a boundary between tumor and normal brain is reached. As previously noted, this boundary may be indistinct with

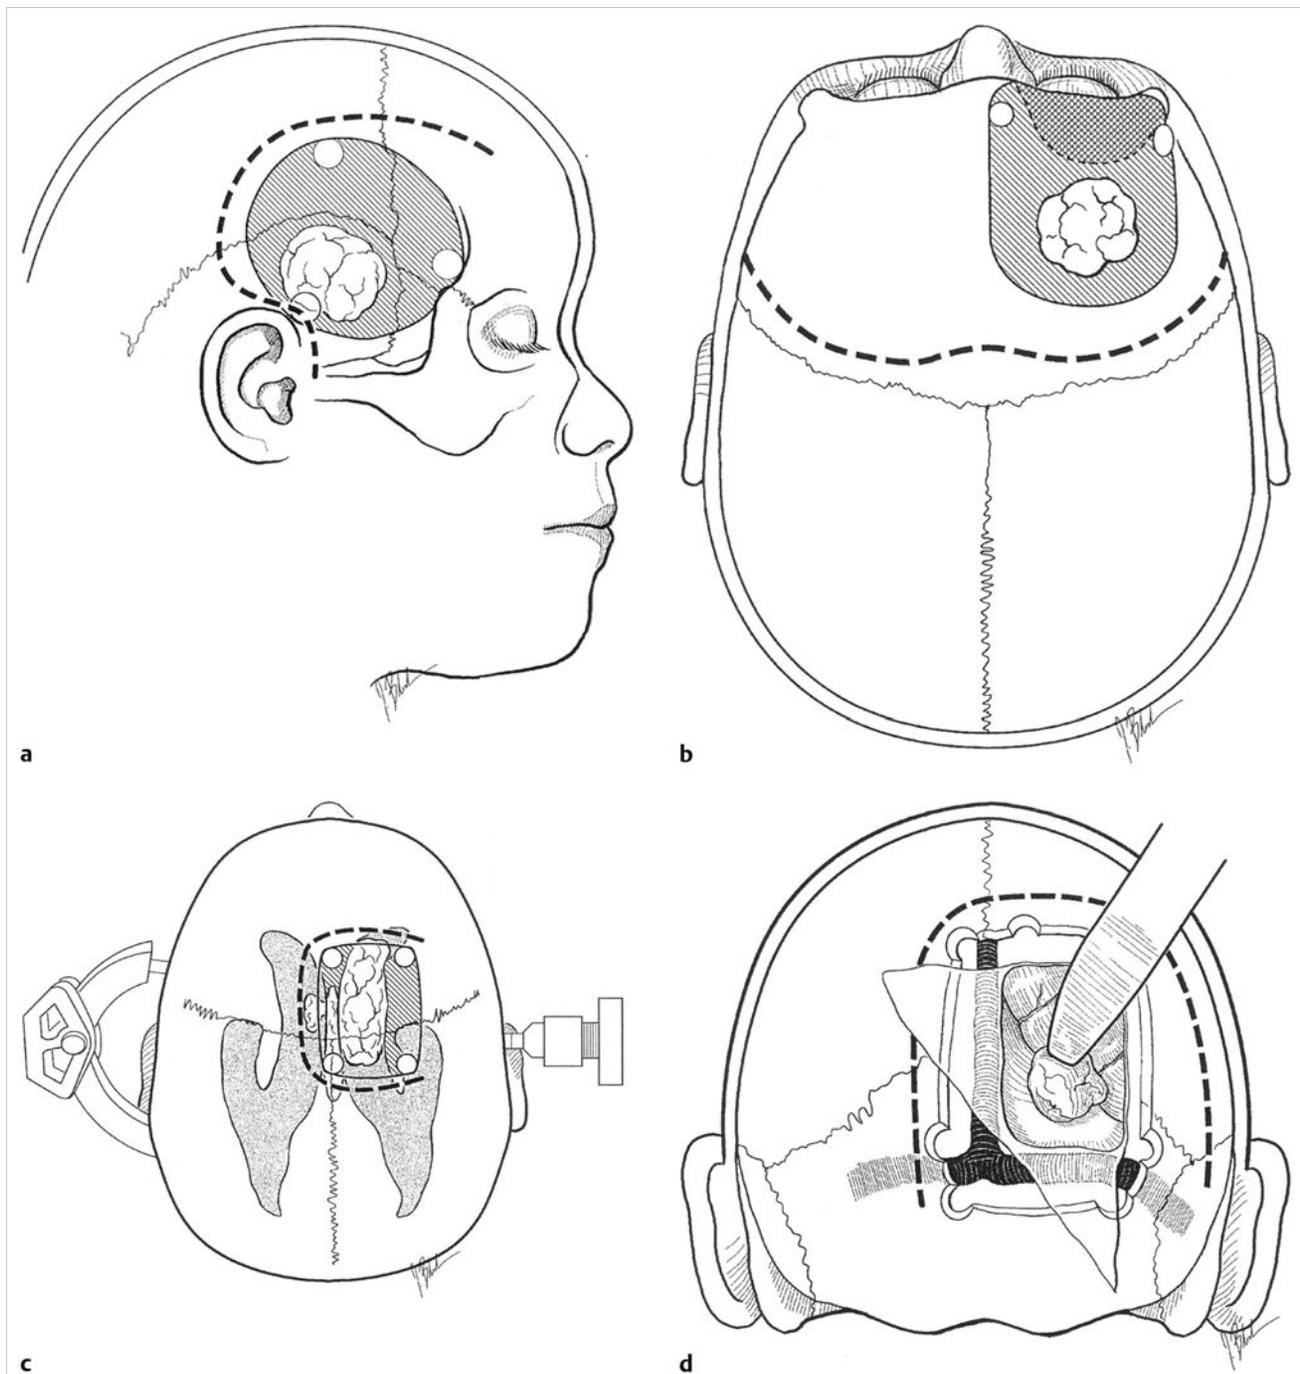

Fig. 34.4 Skin incisions (indicated as dashed lines) and operative approaches for supratentorial hemispheric lesions in various locations. (a) Temporal lesion. (b) Low frontal lesion. (c) Medial hemispheric or intraventricular lesion. (d) Occipital lesion.

infiltrative lesions, and a complete resection may be impossible without unacceptable morbidity.

An important caveat in attempting to achieve a gross total resection concerns the management of cystic low-grade gliomas. For lesions with a well-defined mural nodule in which the cyst lining is nonenhancing and translucent, resection of the wall is unnecessary.⁴¹ In contrast, for lesions in which the wall is thick and enhancing, removal of this component of the tumor is essential, if feasible, to optimize the chances for disease control.

Similarly, pleomorphic xanthoastrocytoma and desmoplastic infantile ganglioglioma often show extensive attachment to the leptomeninges, which (if safely feasible) should be removed along with the tumor to minimize the risk for recurrence. The large size and dense vascularity of desmoplastic infantile gangliogliomas and their typical origin in infants mandates that particularly close attention be directed to obtaining adequate arterial and central venous monitoring and intravenous access before the resection is begun, and to ensuring appropriate

blood and clotting factor replacement, because death from hypovolemia or coagulopathy has historically been a significant risk.⁵

A final point in the overall surgical plan concerns the importance of postoperative imaging to determine the extent of resection. For virtually all types of pediatric hemispheric gliomas, the extent of residual disease is a major predictor of outcome. In this context, if the initial operation was undertaken with the goal of achieving a gross total tumor removal and postoperative imaging discloses that a potentially resectable lesion has inadvertently been incompletely removed, consideration may be given to embarking on another attempt at gross total resection before proceeding with any adjuvant therapy.

34.7 Outcome, Prognostic Factors, and Adjuvant Therapy

34.7.1 Low-Grade Pilocytic and Nonpilocytic Astrocytomas

Studies indicate that the three most important determinants of outcome in children with low-grade cerebral hemispheric astrocytomas are tumor histology, extent of resection, and tumor location (superficial vs. deep). However, these factors are all interrelated, which has complicated efforts to confirm that any single factor is independently predictive of outcome. For example, it is generally held that children with pilocytic astrocytomas have a better prognosis than those with nonpilocytic low-grade gliomas. However, a confounding factor that favors better outcomes with pilocytic tumors is that these lesions are generally well circumscribed and amenable to gross total resection, which is less often the case with nonpilocytic gliomas. Because resection extent is strongly associated with outcome for low-grade gliomas,^{20,34,36,37} it has been difficult, based on

previous studies, to exclude the possibility that pilocytic tumors have a better outcome simply because of their increased resectability. In this regard, results of a large natural history study from the Children's Cancer Group (CCG9891) and Pediatric Oncology Group (POG8930) in more than 500 patients highlighted that outcome was most significantly influenced by resection extent, independently of histology.³⁷

A related issue is whether resection extent is the direct cause of the more favorable outcomes of certain low-grade gliomas, or whether tumors that are amenable to gross total resection (by virtue of their well-circumscribed growth characteristics) merely represent an inherently more favorable biological group. Because there is no ethical way of settling this issue in a randomized format, it will continue to be difficult to prove that resection extent is the primary *determinant* of outcome in childhood gliomas, rather than merely a *correlate* of outcome. In this context, deep-seated (e.g., thalamic) gliomas have historically had a worse outcome than more superficial hemispheric lesions,³⁷ which may simply reflect that the former tumors are more difficult to resect completely or, alternatively, that these lesions constitute a biologically more aggressive group.

The above issues notwithstanding, there is sufficient indirect evidence to support the concept that complete resection of low-grade gliomas of childhood is a worthy operative goal, if safely attainable (► Fig. 34.5). After an extensive resection, with removal of radiologically detectable tumor, the 5-year progression-free survival (PFS) rate exceeds 75%, and in many studies, it approaches 100%.^{34,36,37,42,43} By comparison, the 5-year PFS rate for children with incompletely resected tumors not treated with radiotherapy is approximately 50 to 80%.^{34,37,42} However, the overall 5-year survival rate for children with subtotaly resected low-grade gliomas exceeds 90%, which is substantially better than results observed in adults.^{20,21,34,37,42} In large measure, this reflects that progressive low-grade gliomas in adults commonly exhibit malignant degeneration.^{20,21} This

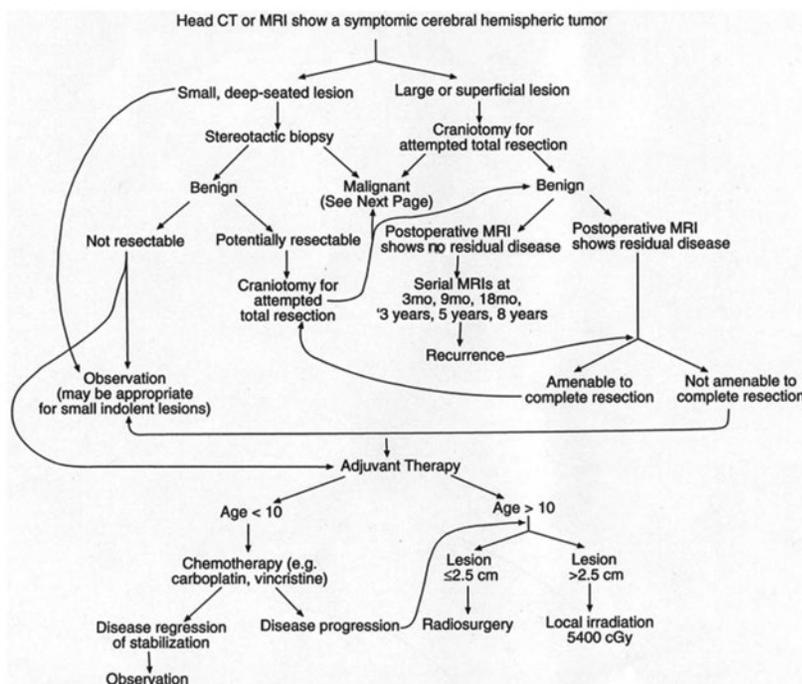

Fig. 34.5 Management protocol for low-grade hemispheric gliomas. CT, computed tomography. MRI, magnetic resonance imaging.

phenomenon occurs less frequently in pediatric low-grade gliomas, which generally remain histologically benign at progression and respond well to additional therapeutic approaches.³⁴ The striking difference in overall outcome between children and adults with low-grade gliomas probably results from differences in the biological characteristics of the tumors in these two age groups.

The value of radiotherapy for patients with low-grade hemispheric gliomas has long been a subject of controversy. Although a beneficial effect of radiotherapy on survival has been detected in adult patients with subtotally resected low-grade gliomas,^{20,44} a survival advantage is less clear for adults undergoing gross total tumor resection or for children undergoing total or nearly total tumor removal.⁴⁵ Efforts to address this issue in a randomized format have been complicated by difficulties with patient accrual. However, in view of the generally favorable outcomes of children who have undergone gross total tumor resection, there is little rationale to proceed with adjuvant therapy. A similar argument has been made for children who have had extensive subtotal tumor removal because many patients remain free of progression for extended periods. In those with progression, the tumor can often be completely resected at a subsequent operation.^{34,36,37,46} In our institutional series, the use of radiotherapy after an initial incomplete resection had a significant impact on PFS but had no influence on overall survival.³⁴ With a median follow-up of more than 8 years, 6 of 33 patients who received radiotherapy had disease progression, compared with 7 of 16 patients not receiving radiotherapy ($p=0.014$). Overall survival, however, was actually better in the latter group because three of the patients who received irradiation developed malignant lesions within the treatment fields, a change observed in none of the patients who did not receive irradiation.

The observation that pediatric low-grade gliomas may remain quiescent after an incomplete resection suggests that a subgroup of tumors exhibits decelerating growth kinetics over time, which fits with recent observations that tumor cells with *BRAF* alterations may undergo senescence after an initial period of growth.¹⁹ In view of this biological variability, many surgeons prefer to follow patients with small amounts of residual disease in an expectant fashion, intervening only in the event of tumor progression. In such cases, re-exploration and complete resection are sometimes feasible^{34,36,46}; if not, adjuvant therapy may then be employed.

A further rationale for deferring radiotherapy after an initial aggressive resection is based on the potential morbidity of this therapy. First, it has been observed anecdotally that incompletely resected gliomas that have been radiated seem to show an increased incidence of malignant transformation,^{34,47} although this may reflect an underlying predisposition of such tumors. Second, external beam radiotherapy has known risks to the developing nervous system in the form of cognitive delay, endocrinopathies, and vasculopathy.^{48–50} Accordingly, chemotherapy is often used to defer irradiation in young children. Although this approach has been applied most extensively in children with unresectable midline tumors, such as chiasmatic-hypothalamic gliomas,⁵¹ favorable results have also been

obtained in children with unresectable hemispheric tumors. A variety of chemotherapeutic approaches have been utilized for these tumors.^{51–53} The efficacy and tolerability of two regimens, carboplatin–vincristine and 6-thioguanine–procarbazine–lomustine–vincristine, were recently compared in the A9952 study of the Children’s Oncology Group and a follow-up study (ACNS0223) that built upon the carboplatin–vincristine regimen by adding temozolomide, another potentially active agent. Results from the latter study are pending at this time. Recent studies have also examined biological therapeutics, including antiangiogenic agents such as bevacizumab and lenalidomide, and agents directed against the dysregulated growth signaling pathways observed in these tumors.^{8,9,54}

Alternate strategies that have been applied to treat foci of unresectable tumor include stereotactic radiosurgery^{55,56} and interstitial radiotherapy,⁵⁷ in which a high dose of radiation is administered to a precisely defined location, thereby minimizing exposure of the surrounding normal brain to radiation. Because radiosurgery provides treatment in a single fraction without the need for an open operation, this approach has been more widely applied. Although preliminary results with both techniques are encouraging, more extended follow-up will be needed to determine whether these approaches are truly beneficial in terms of prolonging long-term PFS and avoiding the potential for late malignant transformation.

The above alternatives notwithstanding, conventional radiation remains a worthwhile option for children older than 10 to 12 years with large areas of unresectable disease, in whom the risks for morbidity may be lower.⁴⁹ New methods of delivering fractionated radiotherapy in a conformally oriented treatment field with three-dimensional image-based treatment planning and narrow peritumoral margins have been developed to minimize treatment-induced morbidity without sacrificing disease control.^{58,59} This approach is currently being evaluated in further detail in a cohort of children in the Children’s Oncology Group ACNS0221 study.

An additional issue that is critical in defining the functional outcome of children with hemispheric low-grade astrocytomas is seizure control. Because many patients present with seizures and a sizeable subgroup have intractable epilepsy, measures directed at achieving postoperative seizure control are of significant therapeutic importance. The merits of *lesionectomy* versus formal epilepsy operations remain a subject of some debate. Several groups have reported favorable results in terms of seizure control after simply resecting the tumor.^{36,60} Others, however, have noted that patients with long-standing, medically intractable seizures benefit from perioperative and intraoperative mapping of seizure foci to guide a more extensive resection to achieve long-term seizure control without medications.^{38,61,62} Our preference has been to use thorough preoperative noninvasive and, if needed, invasive monitoring with subdural grid and strip electrodes to localize epileptogenic foci before undertaking tumor resection in patients with medically intractable epilepsy in association with a cortical tumor. This information is typically supplemented by intraoperative postresection electrocorticography to facilitate the removal of potentially epileptogenic cortex near the tumor, if safely feasible.

34.7.2 Pleomorphic Xanthoastrocytomas

These tumors typically have a favorable long-term prognosis, with an actuarial survival of approximately 90% at 5 years and almost 80% at 10 years. However, several histologic factors appear to adversely influence outcome, including necrosis and increased mitotic activity.^{3,63,64} Several studies have noted that extent of resection has the strongest association with outcome; long-term survival has been reported in 90% of patients undergoing gross total resection versus 65% of those undergoing incomplete resection.^{64,65} Tumors that recur after an initial resection may show evidence of more anaplastic features at reoperation, indicating that these lesions exhibit a potential for malignant progression. Because the value of adjuvant radiotherapy for incompletely resected lesions remains uncertain,^{3,64} there is a rationale to avoid irradiation initially and to repeat resection in children who subsequently develop disease progression (► Fig. 34.5).

34.7.3 Subependymal Giant Cell Astrocytomas

This highly characteristic tumor type arises in children with tuberous sclerosis. Most lesions are indolent and require treatment only if they attain a large size or obstruct the ventricular system. Because these tumors may have an abundant vascular supply and deep venous drainage, significant morbidity can result from attempts to remove them, and care must be taken in achieving meticulous hemostasis and avoiding inadvertent occlusion of major venous tributaries. The prognosis for long-term disease control is excellent after total or nearly total resection⁶⁶ (► Fig. 34.5). If a free communication between the lateral and third ventricles can be obtained, such patients often remain shunt-independent. In contrast, subtotally resected lesions do show a propensity to enlarge over time.⁶⁷ However, patients rarely die because of progressive tumor growth; many such lesions can be extensively resected at a subsequent operation. Radiotherapy or stereotactic radiosurgery has been used anecdotally for the management of unresectable recurrent lesions, but the long-term efficacy of these approaches is uncertain. More recently, the use of molecularly targeted therapy against the dysregulated mTOR signaling that characterizes these tumors has demonstrated a high rate of disease response and short-term tumor control,^{8,9} although the long-term efficacy of this approach as an alternative to surgery remains to be defined.

34.7.4 Oligodendrogliomas and Mixed Oligoastrocytomas

Oligodendrogliomas and mixed oligoastrocytomas of childhood show many similarities to astrocytomas in terms of their often indolent natural history and their favorable response to surgical therapy. Lesions that are well circumscribed are amenable to complete resection and are associated with an excellent long-term prognosis in children, which exceeds the outcomes observed in adults.^{34,68–70} The 5-year survival rate is in the range of 90%. For subtotally resected lesions, the benefit of

radiotherapy versus expectant management remains uncertain. Several groups have reported that incompletely resected oligodendrogliomas of childhood show a low incidence of disease progression.^{34,68} The use of involved-field conventional radiotherapy in patients with postoperative residual disease remains controversial. Because of the uncertain benefits of radiotherapy and the potential risks, our own preference has been to follow children who have known residual disease with serial scans. Further intervention is reserved for those patients who exhibit tumor progression (► Fig. 34.5). Because oligodendrogliomas that manifest with seizures often have an indolent course,^{68,69} long-term follow-up of such patients is often required to rule out progression. In contrast, lesions that present with intracranial hypertension or severe neurologic deficits may have a more aggressive course and account for the small subgroup of oligodendrogliomas that progress over time to higher-grade lesions. Tumors that have anaplastic features at diagnosis generally follow a rapidly progressive course and warrant postoperative therapy with a combination of adjuvant chemotherapy and radiotherapy, as described later for malignant gliomas.^{69,72–74} Although deletions of chromosomes 1p and 19q have been associated with a favorable response to adjuvant therapy in adults with these tumors,^{72,73} no such correlation has been apparent in childhood lesions.⁷⁵

34.7.5 Gangliogliomas and Benign Neuroepithelial Tumors

Because these lesions are usually well circumscribed, complete resection can often be achieved, and the 5-year survival rate exceeds 90%.^{37,76} The efficacy of radiotherapy for incompletely resected benign gangliogliomas remains unclear. Because these lesions tend to be extremely indolent, adjuvant therapy is probably appropriate only for those tumors that subsequently progress and are felt to be unresectable (► Fig. 34.5).⁷⁷

Dysembryoplastic neuroepithelial tumors are also indolent lesions with a favorable long-term outcome. These tumors are generally well circumscribed and often are amenable to complete resection. However, even after an incomplete resection, long-term PFS is common, and adjuvant therapy is often deferred.⁴ Because both gangliogliomas and dysembryoplastic neuroepithelial tumors often present with intractable epilepsy,^{76,78} postoperative seizure control is an important element in evaluating long-term functional outcome. As with supratentorial low-grade astrocytomas, preoperative and intraoperative measures to localize and resect epileptogenic foci in the vicinity of the tumor may have a role in improving ultimate seizure control.⁷⁸

In contrast to the above groups of tumors, which frequently manifest with a seizure disorder, desmoplastic infantile gangliogliomas often present with symptoms of increased ICP resulting from rapid tumor growth. Although complete resection of these well-circumscribed lesions is the therapeutic goal and is associated with a favorable prognosis for long-term PFS,^{79,80} their large size and profuse vascularity may necessitate a subtotal resection in certain cases. Because incompletely resected lesions often progress, several groups have favored administering adjuvant chemotherapy to patients with obvious residual

disease.⁵ This issue is controversial, however, and other groups advocate expectant management and re-exploration in the event of tumor progression because spontaneous regression of the residual tumor has sometimes been observed.^{81,82}

34.7.6 High-Grade Gliomas

These lesions have conventionally been treated with maximal resection followed by radiotherapy to the tumor bed and a margin of surrounding brain, with a dosage of 5,000 to 6,000 cGy in fractions of 180 to 200 cGy/d. The median survival rate for children with these tumors is in the range of 12 to 42 months, with a PFS of only 7 to 18 months.^{33,35,83–86} In recent studies using contemporary classification guidelines for eligibility, fewer than 20% of children have survived for 5 years without disease progression,^{33,84} a decrease compared with historical studies that used less rigorous entry criteria.^{35,86,87}

Adjuvant chemotherapy appears to have some utility in improving the chances for long-term survival, although the optimal treatment regimen remains to be determined. In a prospective controlled study (CCG-943), children who received radiation followed by lomustine, vincristine, and prednisone had a 5-year event-free survival (EFS) rate of 46% versus 18% for patients treated with radiotherapy alone.⁸⁶ In a subsequent study (CCG-945), a more complex eight-drug regimen failed to improve survival further.³⁵ It was presumed to reflect that the dose intensity of several components of the “eight-in-one” experimental regimen was low. This provided the impetus for a series of subsequent studies that examined the efficacy of more intensive regimens. In many cases, chemotherapy in a neoadjuvant (before irradiation) format was applied, or highly intensive regimens that coupled marrow-ablative chemotherapy with autologous bone marrow or peripheral blood stem cell reconstitution were employed. Although some studies suggested an improvement in outcome with this approach,⁸⁸ the results were less convincing in others, and the increased toxicity compared with conventional chemotherapy dampened enthusiasm for this strategy.⁸⁹ Subsequently, CCG-9933 compared three submyeloablative regimens, combining etoposide with either carboplatin, ifosfamide, or cyclophosphamide, but noted an unacceptably high rate of early disease progression, with a PFS rate of 15% at 24 months.⁸⁴ Results with several other neoadjuvant regimens in other cooperative group trials were equally disappointing.

In view of these results, subsequent studies have focused on attempting to enhance the efficacy of postradiation chemotherapy by administering active agents concurrently with irradiation. The ACNS0126 study administered temozolomide daily during irradiation and on a cycle of 5 days per 28 days after irradiation, patterned after the positive results obtained in an adult trial with this approach.^{31,90} Although the results in the pediatric trial were comparable with those in the adult study, they were no better than those in historical trials in which lomustine and vincristine were used.^{33,35,91} A subsequent study, ACNS0423, added lomustine to the postradiation component of therapy, although it remains to be determined whether outcome results were improved.⁹²

Despite the relatively limited advances that have been made in the adjuvant management of malignant gliomas, cooperative

group studies have provided useful information from the surgical perspective, calling attention to an association between resection extent and outcome. In the CCG-945 study, the 3-year EFS rate was 54% for patients undergoing tumor resection of more than 90% versus 17% for patients undergoing biopsy.⁹³ However, it was impossible to exclude the possibility that certain tumors with more favorable biological characteristics were inherently more amenable to extensive resection. In that regard, a subset of childhood malignant gliomas, particularly those occurring in infants, are sufficiently well circumscribed to be amenable to gross total resection,^{83,94} suggesting that they may be biologically distinct from more typical malignant gliomas.

An additional factor that has been associated with outcome in childhood malignant gliomas is tumor histology; patients with glioblastoma multiforme fare worse than those with anaplastic astrocytoma, with 5-year EFS rates in the range of 10% and 20%, respectively.^{35,86,87} Several studies have also noted that anaplastic gliomas with a substantial oligodendroglial component have a more favorable outcome than predominantly astrocytic malignant gliomas.³⁵ This may partially result from a greater sensitivity of the mixed lesions to conventional chemotherapeutic agents, such as the combination of procarbazine, lomustine, and vincristine. As noted earlier, chemosensitivity in adult oligodendroglial tumors appears to be selectively observed in lesions that exhibit deletions involving chromosomes 1p and 19q,^{72,73} although this correlation has not been confirmed in pediatric lesions.⁷⁵ Other molecular features, such as MGMT overexpression,^{32,33} TP53 mutations or overexpression,^{26,95} and high proliferation indices,⁹⁶ have been adversely associated with prognosis independently of histology.

The predominant site of disease progression for supratentorial malignant gliomas is at the primary site, which may be amenable to treatment by additional local therapy, such as surgical resection or stereotactic radiosurgery, followed by adjuvant chemotherapy. Despite aggressive therapy, the prognosis for long-term survival in such children is poor, reflecting the failure of current therapies to substantially slow the course of tumor growth in most patients. Cerebrospinal fluid dissemination of tumor is detected in as many as one-third of such children,⁹⁷ which further lowers the chances for achieving disease control. Improvements in the outcome of these patients will depend on identifying and implementing novel therapeutic approaches that target the molecular pathways that are aberrantly activated in these tumors. Although studies to date in which therapies targeted at both epidermal growth factor receptor (EGFR) and platelet-derived growth factor receptor (PDGFR) have been disappointing,^{98,99} novel agents attacking other signaling mediators, such as PI3K and Akt, are currently under evaluation. An alternative approach involves directly targeting cell surface receptors that are uniquely expressed by glioma cells versus normal brain via the convection-enhanced delivery of immunotoxins directly into the tumor bed and peritumoral brain.¹⁰⁰ In addition, strategies to induce host immunologic responses against malignant gliomas have yielded promising preliminary results in both adult and childhood gliomas, and multi-institutional pediatric trials are under development.^{101–105}

Pearls

- Cerebral hemispheric tumors of childhood differ from those of adulthood in terms of their histologic distribution.
- There is a strong association between extent of resection and outcome for virtually all types of pediatric hemispheric tumors, including malignant lesions.
- An important consideration in selecting the optimal approach to a supratentorial hemispheric lesion centers on developing clear goals of the operation (e.g., biopsy, reduction of mass effect, major cytoreduction, and/or treatment of hydrocephalus), which are influenced by the growth characteristics of the tumor as depicted by CT or preferably MR imaging.
- For patients with well-circumscribed hemispheric tumors, a gross total resection should be the operative goal, if this can be achieved without inordinate risk.
- Several adjuncts have become available during the last several years, including neuronavigation, intraoperative imaging, and neurophysiologic monitoring, that facilitate the extensive removal of lesions previously thought to be unresectable, or resectable only with substantial morbidity.
- After a gross total or nearly total resection, low-grade gliomas can be managed expectantly; adjuvant therapy is reserved for the small percentage of tumors that progress. In contrast, high-grade lesions require intensive multimodality treatment after surgical resection.

35 Supratentorial Nonglial Hemispheric Neoplasms

Scott D. Wait, Frederick A. Boop, and Paul Klimo Jr.

Supratentorial non-midline tumors of nonglial origin are a diverse group of neoplasms and constitute a substantial proportion of all childhood brain tumors. The incidence of those that are not glial in origin (i.e., astrocytomas, ependymomas, others) is difficult to assess, which is due, in part, to our evolving understanding of the molecular infrastructure of these tumors, their postulated cells of origin, and—ultimately—one's definition of what is a glial versus a nonglial tumor. For example, should gangliocytomas be considered neural or glial tumors? Supratentorial tumors in general represent 22 to 54% of all pediatric brain tumors, and of these, about half are glial in origin; the remaining nonglial tumors are an interesting collection of many different types of pediatric brain tumors.^{1–5} Primitive neuroectodermal tumors (PNETs) represent about 5 to 10%, as do gangliogliomas, whereas other tumors occur in the 1 to 2% range and include choroid plexus papillomas/carcinomas (CPPs/CPCs), teratomas, dysembryoplastic neuroepithelial tumors (DNETs), meningiomas, germinomas (excluding those in pineal and suprasellar locations), sarcomas/chondromas, metastatic lesions, and lymphomas. Again, accurate statistics are difficult to obtain as these data are gleaned from case reports and from parts of larger mixed-case series. Nonetheless, unusual tumors occur in the supratentorial location and should be considered while treatment is being planned.^{1–3,5,6}

This chapter focuses on the main nonglial hemispheric tumors, including PNET, ganglioglioma/gangliocytoma/desmoplastic infantile ganglioglioma, DNET, CPP/CPC, meningioma, and—briefly—other rare tumors, such as central neurocytoma, germ cell tumors, metastatic malignancies and lymphoma.

35.1 Supratentorial Primitive Neuroectodermal Tumors

Supratentorial PNET is a relatively rare but challenging diagnosis that accounts for approximately 2.5 to 6% of all pediatric tumors.⁷ These tumors have a propensity for rapid growth, and thus the duration of symptoms is usually relatively short. The symptoms often include nonlateralizing signs of elevated intracranial pressure. Compared with medulloblastoma (the infratentorial equivalent of supratentorial PNET), supratentorial PNET has consistently demonstrated a worse prognosis, with 5-year survival rates ranging from 30 to 75% despite maximal therapy.^{7–12} These rates suggest an intrinsic biological difference between supratentorial and infratentorial PNETs.¹³ Originally, the etiologic cell of origin for PNETs was considered to be a primitive neuroepithelial cell capable of differentiating into neuronal, glial, and ependymal cell lines. The expression of *SOX2*, *NOTCH1*, and *ID1* is upregulated and the *JAK/STAT3* pathway is activated in supratentorial PNET, indicating a glial tumorigenesis. Conversely, the activation of proneural bHLH transcription factors is upregulated in infratentorial PNET, indicating a neuronal tumorigenesis.^{14–16}

35.1.1 Imaging and Preoperative Evaluation

PNETs are generally hyperdense on computed tomography (CT) and isointense (or hypointense) to brain on magnetic resonance (MR) imaging, with avid—but often heterogeneous—enhancement (► Fig. 35.1). A recent study of PNETs in children (i.e., patients younger than 20 years of age) suggests that there is about a 15 to 20% incidence of nonenhancement. The center of the tumor is often heterogeneous, with cysts and/or areas of necrosis.^{17–19}

Staging should be performed preoperatively by imaging the entire neuraxis. At initial presentation, 10 to 20% of patients will have disseminated disease.^{9,20–22} Lack of dissemination by imaging should be confirmed by cerebrospinal fluid (CSF) cytology analysis, but this is usually done postoperatively once the mass lesion has been removed.²³

35.1.2 Treatment and Outcome

PNET requires multimodal therapy, including surgical extirpation, craniospinal irradiation, and chemotherapy. Traditionally, all patients with supratentorial PNET were categorized as having high-risk disease, and survival rates have been less than 50% in most studies. Recently a multi-institutional group has stratified patients into average- and high-risk groups based on the following: age younger than 3 years, subtotal resection (i.e., more than 1.5 cm² residual), and leptomeningeal dissemination.²⁴ Patients without these risk factors are termed “average risk”; the presence of any one of these factors will place a patient in the “high-risk” category. When this stratification and treatment with risk-adjusted craniospinal irradiation with additional radiation to the primary tumor site and subsequent high-dose chemotherapy supported by stem cell rescue are used, the 5-year survival outcomes are 60% for high-risk patients and 75% for average-risk patients.

In general, patients should undergo maximal safe tumor resection, high-dose radiation to the tumor bed, some form of craniospinal radiation (\pm risk adjustment), and subsequent chemotherapy (\pm stem cell rescue).^{7–9,12,24–29} There are efforts under way to treat patients with resection and chemotherapy alone in order to delay, or altogether avoid, the potential costs of radiotherapy (RT), particularly in patients younger than 5 years of age.³⁰ Rates of 5-year event-free survival (EFS) and overall survival (OS) were 39% total for high- and low-risk patients (24% for high-risk patients, 53% for average-risk patients), and 49% total for high- and low-risk patients (33% for high-risk patients, 62% for average-risk patients), respectively. In this study, patients with nonpineal supratentorial PNET had a survival advantage over patients with pineal PNET. For patients with RT-naïve, chemoresponsive recurrences, myeloablative doses of thiotepa-based chemotherapy followed by stem cell rescue and RT may still offer the chance of cure.³¹

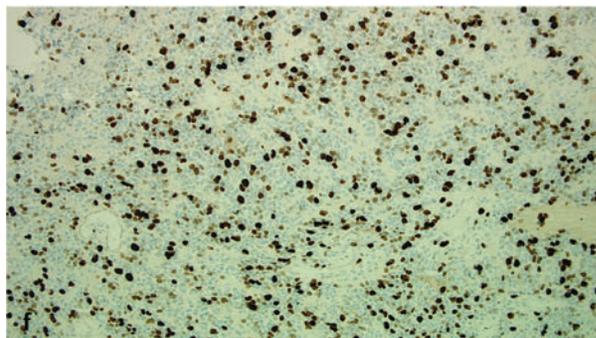

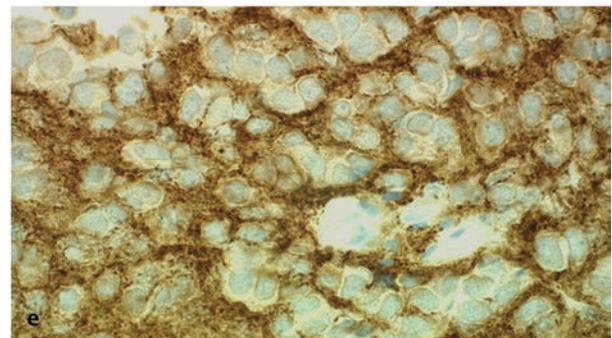

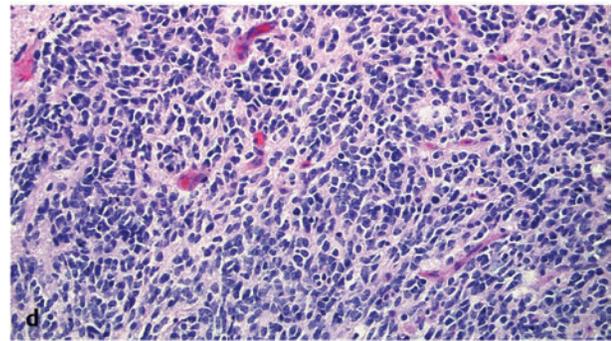

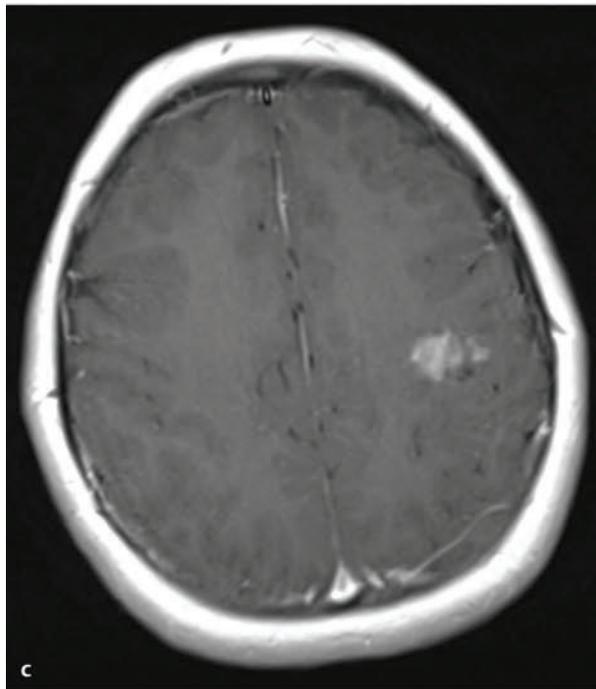

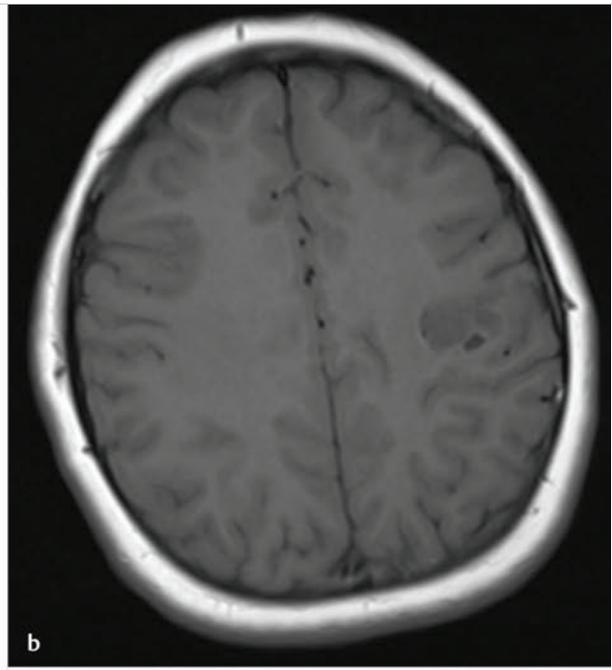

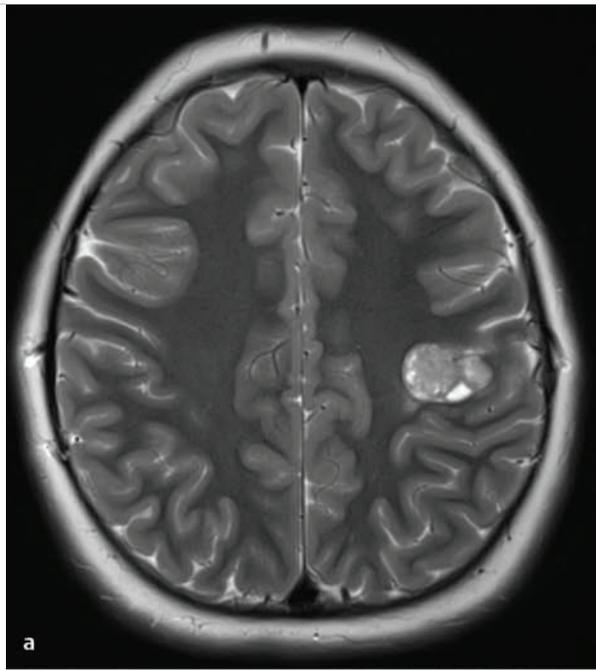

Fig. 35.1 (a) Axial T2 magnetic resonance (MR) imaging and T1 MR imaging (b) with and (c) without contrast of a typically appearing supratentorial primitive neuroectodermal tumor (PNET) in a 9-year-old girl with classic Jacksonian seizures. The tumor is hyperintense on T2 with associated cystic areas. Heterogeneous enhancement is present after gadolinium administration. (d) Supratentorial PNET is hypointense to isointense on T1 imaging without contrast. Hematoxylin and eosin stain (x20) (e) shows a patternless sheet of small cells with positive reactivity to synaptophysin antibodies, (f) indicative of neuronal differentiation and a high rate of cellular proliferation (antibody to Ki-67 protein).

35.2 Glioneuronal Tumors: Gangliogliomas/Gangliocytomas/Desmoplastic Infantile Gangliogliomas

The tumors in this group have subtle differences but are considered together under the term *ganglioglioma*; where significant differences exist, they are detailed. Gangliogliomas are mixed neuronal–glial tumors and account for 4 to 9% of childhood brain tumors; patients often present with seizures, and these tumors account for up to 40% of all tumors responsible for epilepsy.^{32–40} In 1926, the term *ganglioglioma* was coined by O. C. Perkins for tumors composed of dysplastic neurons and neoplastic glia.⁴¹ Although the majority are cystic, temporal tumors in other locations are reported.^{33,34,40,42–44} The World Health Organization (WHO) considers them grade I or II, although anaplasia, necrosis, or an MIB labeling index above 10% can result in an upgrade to anaplastic (III) or malignant (IV).⁴⁵

Desmoplastic infantile gangliogliomas (DIGs) are typically very large lesions arising in the hemispheres, generally in infants. They are often misdiagnosed as malignant astrocytomas or sarcoma-type tumors because of their cellular appearance and mitotic activity.^{46,47} They have a desmoplastic stroma, neoplastic astrocytes and neuronal cells, and may have a high mitotic or Ki-67 indices or areas of necrosis. Despite this more malignant picture, these tumors are WHO grade I.⁴⁸

35.2.1 Imaging and Preoperative Evaluation

The appearance of gangliogliomas on both CT and magnetic resonance (MR) imaging suggests a benign tumor. They are hypodense to brain on CT and show high signal intensity on T2-weighted or fluid-attenuated inversion recovery (FLAIR) images. Enhancement is variable and patchy when present (► Fig. 35.2). The lesion will involve the cortex and underlying white matter and will often be adjacent to dysplastic cortex.⁴⁹ There is often little mass effect or edema. Confirming the relatively indolent and benign nature of the tumor, the inner table of the skull can show some bowing due to the long-term pressure applied by the tumor.^{17,19}

DIG is a tumor of infants that is often massive and located in the frontoparietal areas. The vast majority of the mass effect is the result of intratumoral cysts. On MR imaging, there is typically a solid superficial mass or plaque that is avidly enhancing, with septa originating from the solid tumor. Large portions of the tumor enhance after gadolinium administration, including the solid superficial mass, the walls of the intratumoral cysts, and the multiple septa.^{50,51}

Gangliogliomas are more commonly seen in children; however, they can present later in adulthood. Patients generally present with seizures, although the mass effect rarely causes symptoms. Epilepsy resulting from these lesions is often resistant to medications.³³ Complete resection should be the goal as it results in the best outcomes for seizure and tumor recurrence, but it may not be possible because of tumor adherence to critical neurovascular structures. Fortunately, patients who undergo subtotal resection can also see improvement in their

seizures.^{49,52} Patients with multiple types of seizures or an extended history of seizures are best managed by a multidisciplinary epilepsy service as lesionectomy alone may not be sufficient for seizure control. These patients may require a more extensive imaging work-up, video electroencephalography (EEG) recording from surface or subdural electrodes, or intraoperative electrocorticography (ECoG).

35.2.2 Treatment and Outcome—Tumor Control

In patients whose tumors are amenable to total resection, no further therapy is required, and the risk for tumor recurrence is quite low. Gangliogliomas—including the desmoplastic variant—are generally benign tumors that are essentially cured by total resection.^{40,46,49,52–55} This optimistic view is tempered by the fact that those tumors arising from or extending into midline structures are difficult to resect and are often of a higher grade.^{40,42,56} These children have a higher risk for recurrence, even with radiation therapy. Some authors feel that midline tumors are different pathologically from gangliogliomas that arise in the hemisphere, and that adjunctive therapy, usually radiation, should be administered.^{34,40,42,56–58} However, the numbers involved are small, and at this time, close neuroimaging follow-up is considered acceptable until progression occurs. Pathologic grade and totality of resection are the best prognosticators for tumor control. In a combined series of over 150 pediatric patients with all grades of ganglioglioma, 94% of the patients remained alive at the most recent follow-up, 95% of patients who presented with seizures remained alive, and all patients with intractable seizures remained alive.^{34,57–60} Of patients with midline tumors, 76% remained alive. Ninety-seven percent of patients who had a gross total resection (GTR) remained alive, versus 80% who had a subtotal resection (STR).⁵⁶ Another study, of 42 patients, reported a 56% survival with high-grade tumors and 90% survival with low-grade tumors.⁶¹ Luyken et al reported local control to be significantly improved by a temporal lobe location, lower grade, and GTR.⁴¹ Karremann et al specifically looked at children with anaplastic histology and found an 88% estimated 5-year survival and GTR to be the best predictors of survival.⁶²

A more recent meta-analysis regarding the role of RT, which included many of the above patients, divided patients into four groups: GTR, GTR + RT, STR, and STR + RT.⁵⁴ Children were combined with adults for a sample size of 402 patients (232 patients [58%] ages 0 to 19 years). They calculated 10-year local control and OS for each group: rates of local control were 89%, 90%, 52%, and 65%, respectively, and rates of OS were 95%, 95%, 62%, and 74%, respectively. When high-grade tumors were considered, only local control was significantly improved by adding adjuvant RT to STR. They concluded that there was no role for RT when GTR is achieved, and that RT improved local control of both high- and low-grade incompletely resected tumors and therefore should be considered. Liauw et al had similar findings in their study and noted that salvage RT may be less effective than up-front adjuvant therapy.⁵⁵

DIGs are generally benign and amenable to complete surgical resection; when that can be accomplished, no further

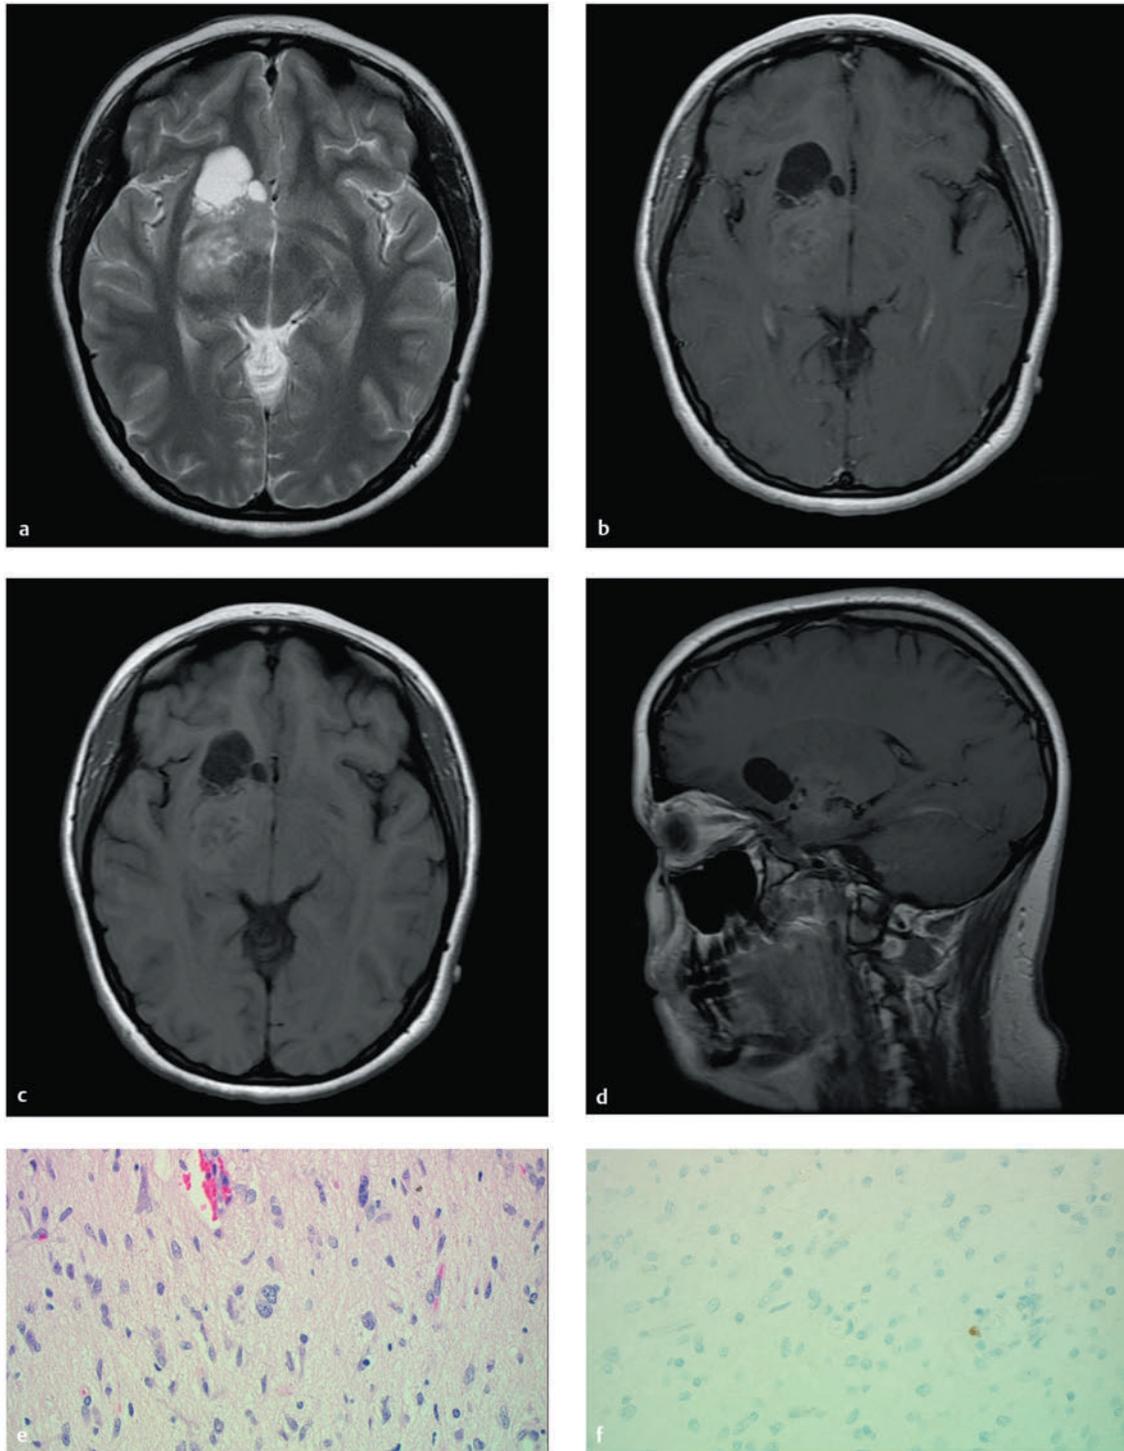

Fig. 35.2 Magnetic resonance imaging of a midline/basal ganglia ganglioglioma in a 17-year-old girl who presented with seizures. (a) Axial T2 image illustrates the typical solid/cystic nature of the tumor and hyperintensity. (b) Axial T1 images with and (c) without contrast demonstrate the enhancement pattern often found in this lesion. (d) The cystic, variably enhancing nature of this difficult tumor is demonstrated again in the sagittal plane with contrast. (e) Hematoxylin and eosin stain (x40) shows disorganized, pleomorphic neurons with binucleation and eosinophilic granular bodies and (f) virtually no cellular proliferation (Ki-67 stain).

therapy is warranted. If an STR is achieved or the tumor recurs, then either observation or re-resection is the appropriate course, respectively.^{50,51} Residual disease usually does not grow and can even spontaneously disappear.⁶³ Malignant

transformation has been reported necessitating chemotherapy.^{64,65} Radiation is typically not an option, given the very young age of the patients and the large treatment volume that would be required.

35.2.3 Treatment and Outcome—Seizure Control

Gangliogliomas are the most frequent cause of tumor-associated drug-resistant epilepsy in children.³³ Both the ganglioglioma itself and the often-associated surrounding cortical dysplasia—present in up to 80%—have been proved to be seizure generators.^{66–69} Patients whose epilepsy is not controlled with medications are excellent candidates for resective surgery. However, the question of whether lesionectomy alone can be performed or whether lesionectomy plus resection of surrounding tissue, including dysplastic cortex, is necessary to achieve optimal seizure control is unresolved. Some authors consider lesionectomy alone to be sufficient,^{36,38,49,52,70,71} whereas other authors suggest, when possible, resecting a margin of tissue around the ganglioglioma.^{35,41,57,67,72–74}

Giulioni et al performed lesionectomy alone on a mixed group of 15 glioneuronal tumors (73% gangliogliomas) and reported an 87% rate of seizure freedom (Engel class I).⁴⁹ They did not note an association with the type or duration of epilepsy, seizure frequency, or completeness of resection. Ogiwara et al took a similar approach in their group of 30 children with gangliogliomas.⁵² However, they used intraoperative ECoG in 21 patients and resected additional tissue if there was abnormal spike activity. When this was done, 11 of 21 patients had additional surrounding tissue removed. Ninety percent of their patients were seizure-free (Engel class I), and they noted no difference between the rates of seizure freedom in those who had ECoG and those who did not. Of note is that two of their three patients who continued to have seizures had lesionectomy alone performed on extratemporal tumors. Patients with extratemporal tumors treated with lesionectomy alone had 82% seizure freedom. In conclusion, regardless of the approach, most patients experience excellent outcomes with regard to their seizures. The use of ECoG and the extent of resection of tumor and surrounding tissue are decisions best made on a case-by-case basis.

35.3 Dysembryoplastic Neuroepithelial Tumors

DNETs were originally described by Dumas-Duport et al in 1988 and are almost universally associated with seizures.⁷⁵ Grossly, they have the appearance of an expanded cortex or a megagyrus; histologically, they show disorganized glial and neuronal elements that are characteristically arranged in a columnar appearance oriented perpendicular to the cortical surface. Cytologic atypia of neurons, a feature typical of gangliogliomas, is absent in DNETs. Foci of cortical dysplasia are found in 50 to 90% of cases.^{60,75–77} DNETs have a predilection for the frontal and temporal lobes and can also be multifocal, but the most common location is the temporal lobe. The presence of cortical dysplasia, young age at the onset of symptoms, and deformity of the overlying calvaria (in up to 60% of cases) suggest that this tumor has a dysembryoplastic origin. Dumas-Duport hypothesized that DNETs arise from the fetal subpial granular layer, an embryologic structure that involutes during the course of normal development.⁷⁸ It is currently accepted that surgery is the only required therapy, even if residual lesion is present or multiple resections are required.^{76,78–80}

35.3.1 Imaging and Preoperative Evaluation

DNETs characteristically appear as well-demarcated, hypodense, and nonenhancing lesions best seen on FLAIR or T2 sequences without peritumoral edema or mass effect (► Fig. 35.3).^{17,79,81} CT will demonstrate calcifications in about a quarter of all cases, and bony remodeling is common.⁷⁵ Almost all patients present with partial complex seizures, and as in patients with gangliogliomas, the seizures are often disabling because of their frequency, potential for secondary generalization, and poor responsiveness to pharmacotherapy.

35.3.2 Treatment and Outcome

The indications for surgery are either to obtain tissue for diagnosis or to control seizures. Most series of DNETs have been reported in terms of seizure outcomes. Engel class I outcomes are reported for 50 to 100% of patients.^{72,75,82–93} Some of these studies include several types of tumors and a mixture of pediatric and adult patients. For example, Chang et al reported a large series of 50 adult and pediatric DNETs with a mean follow-up of 5.6 years.⁸³ Over half of the cases were adjacent to areas of cortical dysplasia. Eighty-six percent of patients were seizure-free at 1 year (Engel I). Engel class I patients represented 80% of the group followed out to 10 years. Class I outcome was associated on multivariate analysis with complete resection and extratemporal location. For cases in which ECoG was used, the presence of extralesional spikes (and resection of that cortex) predicted better seizure control. This same group performed a meta-analysis of all reports of DNET and gangliogliomas in adults and children and found that, overall, 80% of patients were seizure-free after resection.⁹⁴ Short duration of epilepsy (less than 1 year), GTR, and focal seizure type predicted seizure freedom. Pathology (DNET vs. ganglioglioma), lesion location, age, and the use of ECoG were not predictive of seizure freedom. With respect to tumor control, residual tumor may remain dormant for many years, but there are reports of growth of histologically confirmed DNETs on neuroimaging that necessitated reoperation.^{75,95}

35.4 Choroid Plexus Papillomas/Carcinomas

CPPs and CPCs account for 2 to 6% of pediatric brain tumors and 10 to 20% of tumors in children younger than 1 year.^{96,97} The WHO classifies them as grade I (CPP), grade II (atypical CPP), and grade III (CPC).⁹⁸ Papillomas show a histologic architecture similar to that of normal choroid plexus; numerous papillae are covered with a simple columnar or cuboidal epithelium. Carcinomas exhibit brain invasion, nuclear atypia, an increased nuclear-to-cytoplasmic ratio, prominent and numerous mitotic figures, and a loss of the normal papillary architecture. The majority of tumors present with signs and symptoms of hydrocephalus because of their characteristically intraventricular location (most commonly in the atrium of the lateral ventricle) and propensity to overproduce CSF. They rarely present in brain parenchyma or the cerebellopontine angle.⁹⁹ Up to 30% of

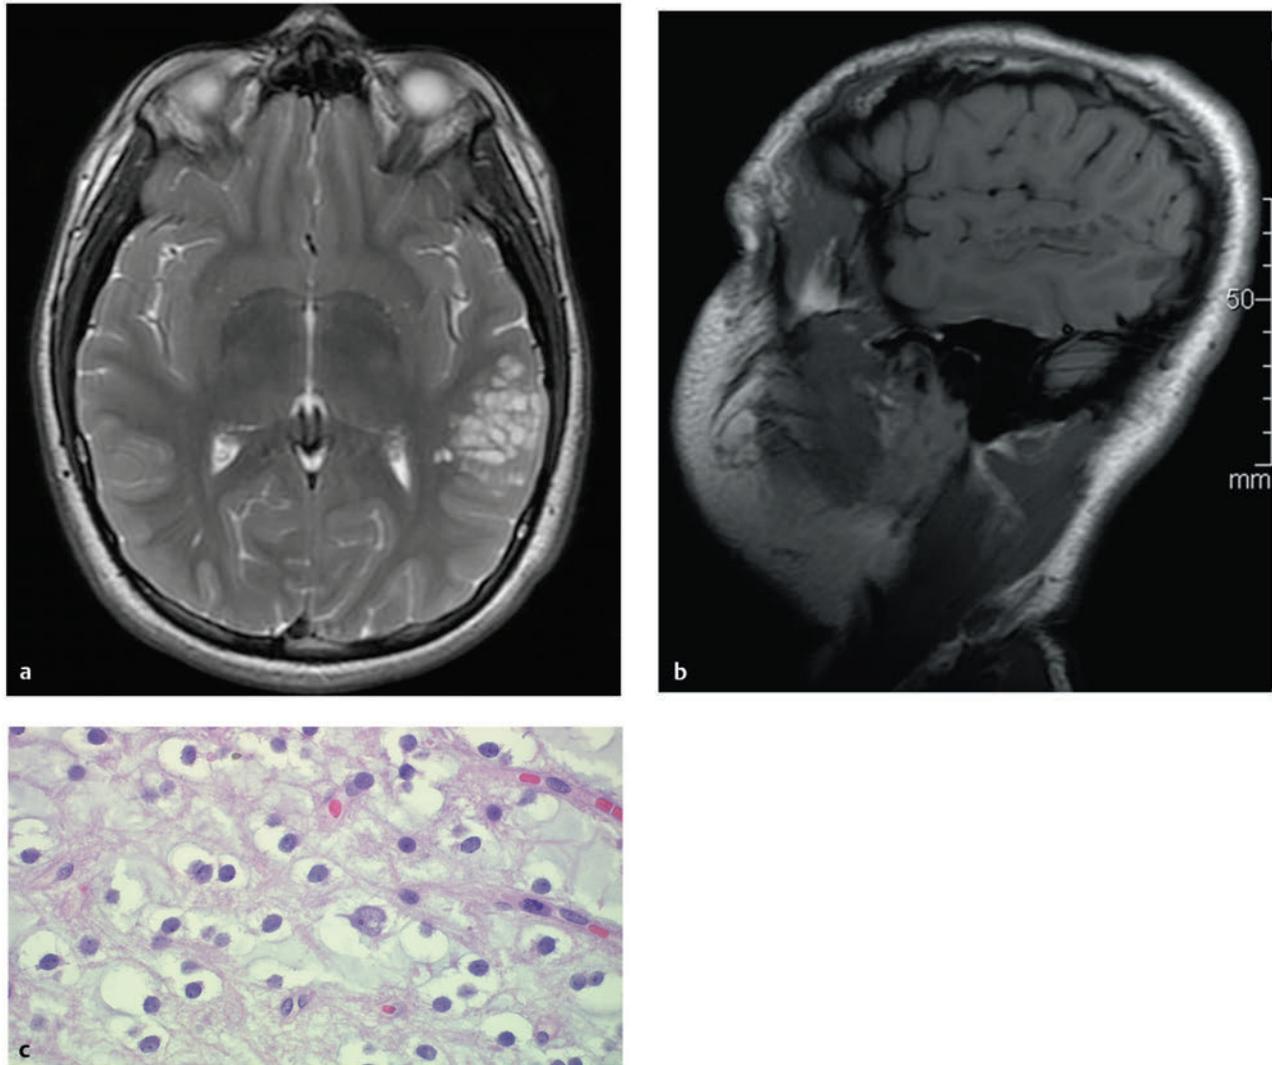

Fig. 35.3 This 13-year-old boy presented with seizures and a dysembryoplastic neuroepithelial tumor (DNET). (a) Axial T2 and (b) sagittal noncontrast T1 magnetic resonance images show the typical appearance of a “bubbly” expanded gyrus that is hyperintense on T2 and hypointense on T1. The lesion does not enhance. (c) “Floating neurons”—cortical ganglion cells sitting in small pools of mucin separated by cortical neuropil—are a common but nonspecific feature of DNETs (hematoxylin and eosin stain, x60).

patients with CPCs have metastatic disease at presentation, necessitating spinal screening for all patients.

35.4.1 Imaging and Preoperative Evaluation

Choroid plexus tumors are isodense to hyperdense to brain on CT and on MR imaging. They have a lobular, cauliflower-like appearance, can be quite large, are hypervascular, and generally enhance avidly with contrast. Hydrocephalus is present in 80% of patients with CPPs. Younger patients are more likely to have supratentorial tumors, whereas patients older than 14 years have a predominance of infratentorial tumors.⁹⁹ The presence of heterogeneity and surrounding edema of the brain raise the possibility that a lesion is a CPC (► Fig. 35.4).¹⁰⁰

35.4.2 Treatment and Outcome

Surgery is the primary treatment for choroid plexus tumors, but this can be challenging because of the hypervascular nature of the tumors coupled with the fact that they are usually found in young children who cannot tolerate excessive blood loss.^{101–105} This has led to preoperative measures to reduce the tumor’s blood supply. Atrial tumors typically have a dual supply from the posterior lateral and anterior choroidal arteries. Third ventricular tumors are supplied by the posterior medial choroidal artery. These arteries may be embolized immediately before surgery, or neoadjuvant chemotherapy, such as ifosfamide, carboplatin, and etoposide, may be administered—more commonly with CPCs—to devascularize the tumor.^{106–108} The neurosurgeon can tailor the surgical approach to coagulate the blood

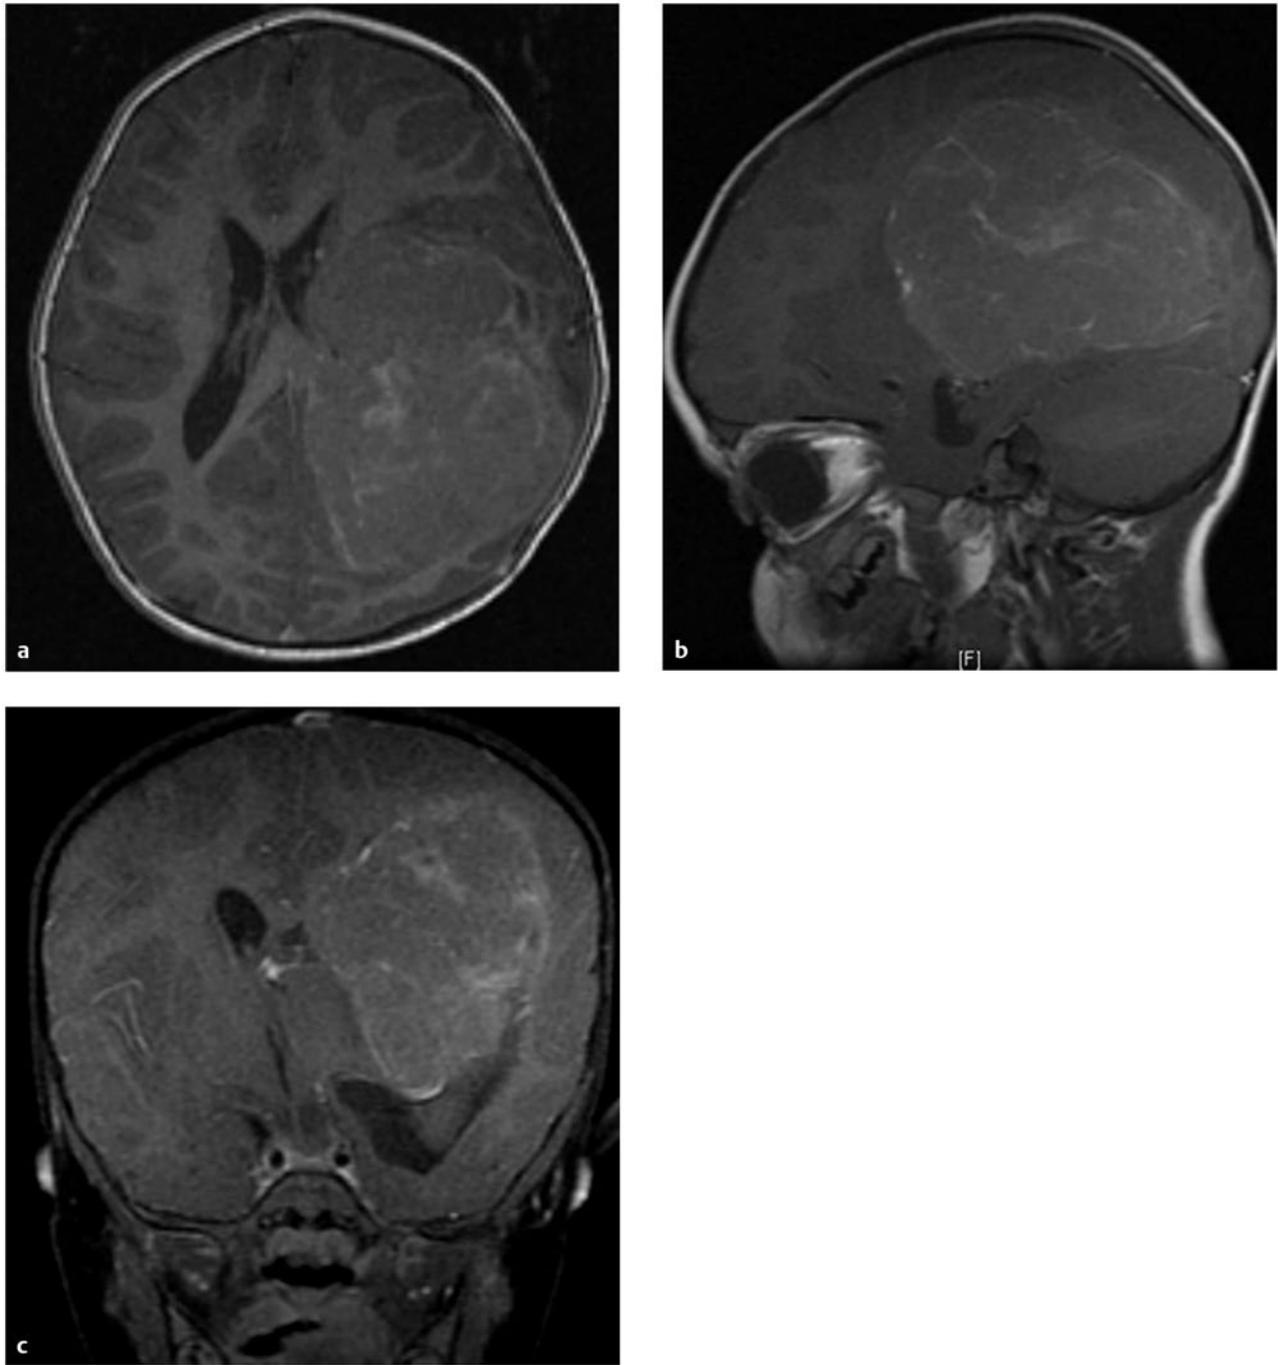

Fig. 35.4 Axial (a), sagittal (b), and coronal (c) gadolinium-enhanced T1 magnetic resonance images of a 4-year-old girl who presented with progressive hemiparesis. This choroid plexus carcinoma (CPC) was resected. The tumor is located within the ventricle, centered in the atrium, and has a variable enhancement pattern that is often suggestive of a CPC.

supply early, before resecting the tumor. If these feeding vessels are not accessible early in the case, then rapid tumor debulking is performed with the expectation that large volumes of blood products may need to be infused and the resection may require a “staged” approach. CPCs are more difficult to resect because they are friable, and a well-developed plane is lacking between the tumor and brain.

If a CPP is totally resected, then no further therapy is indicated.¹⁰⁹ The 5-year survival rate is close to or at 100% in many published series.¹¹⁰ A patient with a CPC who undergoes GTR, rather than STR, has a better chance at long-term survival, but even with GTR, the 5-year survival rate ranges from 30 to 50%. Most authors agree that a completely resected CPC requires adjuvant chemotherapy. For example, a meta-analysis by Wrede

et al found that postoperative chemotherapy resulted in a survival benefit, both with RT and without.¹¹¹ For the subgroup of patients with STRs, 2-year overall survival was better with chemotherapy than without (55% vs. 25%). The addition of RT predicted better survival (47.4% vs. 25.2%). Most authors suggest postoperative chemotherapy for younger patients (i.e., younger than 3 years) and combination chemotherapy and RT for older patients (i.e., older than 3 years).¹¹¹⁻¹¹⁵

CPC is often associated with Li-Fraumeni syndrome, in which patients have a germline mutation of *TP53*, a tumor suppressor gene located on the short arm of chromosome 17.¹¹⁶ This mutation is thought to confer resistance to both RT and chemotherapy.¹¹⁷ Some authors suggest Li-Fraumeni screening of all patients with CPCs.^{109,118} Patients with CPCs without germline *TP53* mutations had a 5-year survival of 82%, compared with 0% if they harbored a mutation.

35.5 Meningiomas

Meningiomas are rare in children, accounting for 1 to 2% of all meningiomas and 0.7 to 4.2% of pediatric brain tumors, but they are becoming more common with an increasing population of long-term survivors of brain tumors who have received cranial irradiation.¹¹⁹⁻¹²⁶ The presentation may include elevated intracranial pressure, the new onset of seizures, and focal neurologic deficit. Pediatric meningiomas are strongly associated with neurofibromatosis type 2 (NF-2) and to a lesser degree neurofibromatosis type 1 (NF-1).¹²⁷ Unlike meningiomas in adults, childhood meningiomas are more commonly seen in the posterior fossa, along the orbital nerve, in the ventricles, and without dural attachment in the brain parenchyma or within the sylvian fissure.¹²⁸ The WHO classifies meningiomas as grade I (typical), II (atypical), and III (anaplastic).^{119,120}

35.5.1 Imaging and Preoperative Evaluation

Pediatric meningiomas are similar to adult tumors with the exception that necrosis and cyst formation are more common in children. They are isodense to hyperdense to brain on CT, with calcification often present. MR imaging often shows an isodense mass that avidly enhances and generally has a dural attachment (► Fig. 35.5). Hyperostosis is present in approximately 50% of children with these tumors. Infantile meningiomas can be very large and are often associated with very large intratumoral cysts.^{17,129} As in choroid plexus tumors, preoperative angiography with embolization may be helpful in detailing the vascular anatomy and decreasing the blood supply in preparation for surgical resection. Conventional angiography or MR venography is also helpful in evaluating sinovenous patency for tumors that involve these structures.

35.5.2 Treatment and Outcome

Some authors feel that meningiomas are more aggressive in children than in adults, given the higher rates of recurrence even after GTR, which is likely the consequence of a higher rate of aggressive histopathology.^{127,130} A recent imaging study found no correlation of cystic components, MR characteristics,

peritumoral edema, or size with histopathologic grade.¹³¹ Because RT has a negative effect on the developing nervous system and radiation-induced tumors have a good outcome after complete resection, total removal of the tumor should be the goal, with focal radiation or stereotactic radiosurgery reserved for recurrences.¹³²⁻¹³⁴ Patients who develop radiation-induced meningiomas have excellent outcomes with single-modality therapy (i.e., surgery or RT), with a 5-year survival of 89%.¹³⁵

35.6 Miscellaneous: Central Neurocytomas, Germ Cell Tumors, and Others

Central neurocytoma is typically thought of as an intraventricular tumor, most commonly occurring in the supratentorial ventricles.¹³⁶ The first report of an extraventricular neurocytoma was in 1989, but this entity was not included in the WHO classification until the 2007 revision.^{137,138} Extraventricular neurocytomas have been described in the cerebellum, brainstem, skull base, and spinal cord but are usually large, well-circumscribed lesions located in the cerebral hemispheres, with a predilection for the frontal and parietal lobes.¹³⁹⁻¹⁴³ A number of pediatric case reports are found in the literature.¹⁴⁴⁻¹⁴⁷ Radiographically, these tumors are well demarcated and can be quite large with heterogeneous enhancement—often cystic and calcified—and they may or may not be associated with edema, hemorrhage, or necrosis.¹⁴⁸ Treatment is complete surgical resection. If this is not possible, then close radiographic follow-up is needed, with radiation reserved as an option for progressive disease or residual disease in older children.¹⁴⁹

Germ cell tumors are rarely hemispheric and therefore are discussed only briefly. They are seen primarily in children and are much more common in the Asian population. In the Caucasian population, 0.5 to 3% of pediatric tumors are of the germ cell type.^{150,151} The incidence is 11% in Taiwan and 5 to 15% in Japan. Most germ cell tumors arise in the pineal or suprasellar region, but they can be seen in the hemispheres or basal ganglia.¹⁵²⁻¹⁵⁷ CSF metastases occur in 3 to 37%; thus, all patients require neuraxis imaging and CSF cytology. Mature teratomas are best treated with surgery alone because they continue to grow and exert mass effect on adjacent structures. Germinomas are best treated with chemotherapy and/or radiation, with surgery reserved for diagnostic purposes when CSF fluid and serum markers (alpha fetoprotein and β -human chorionic gonadotropin) are ambiguous.¹⁵⁸⁻¹⁶³ Multiple studies suggest a cure rate of well over 90% with radiation therapy. Early results for chemotherapy alone in germinoma showed a significant recurrence rate.¹⁵⁹ However, the use of craniospinal radiation in germinoma without dissemination versus ventricular volume radiation is considered controversial, as is the need for chemotherapy after focal radiation alone.¹⁶⁰

Nongerminomatous germ cell tumors are rare. Tumor markers are elevated, and initial therapy is usually chemotherapy followed by resection for residual disease. With complete resection, no leptomeningeal or CSF spread, and aggressive radiation therapy, one should expect a 5-year PFS rate of 60%.^{153,154,161} The presence of metastatic disease is an ominous sign.

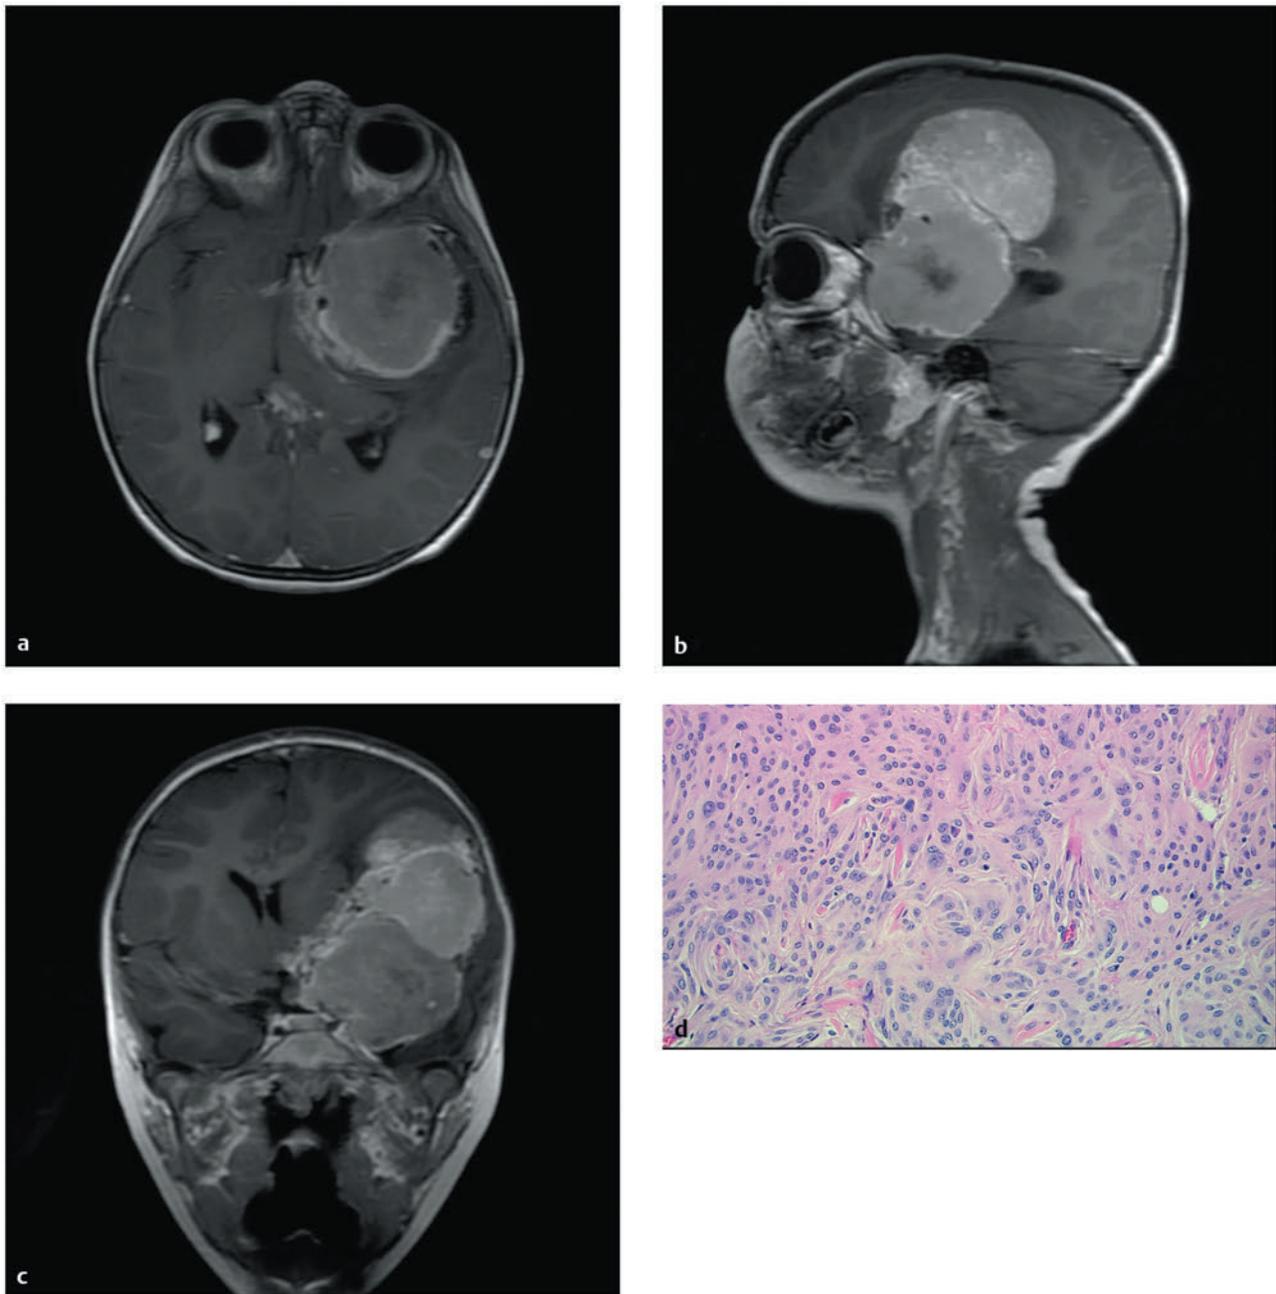

Fig. 35.5 (a) Axial, (b) sagittal, and (c) coronal gadolinium-enhanced T1 magnetic resonance images of a 22-month-old boy who presented with progressive hemiparesis. This large meningioma was resected. Imaging is similar to that of adult meningiomas. The tumor originated from the dura overlying the clinoid and sphenoid wing. (d) Meningothelomatous-type meningioma (hematoxylin and eosin stain, x20) is characterized by whorls, lobules, indistinct cell borders due to interdigitating cell membranes, and intranuclear pseudo-inclusions (pale areas of the nucleus due to cytoplasmic invaginations). There is a mitotic figure in the middle of the picture.

The remainder of the tumors seen in the cerebral hemispheres of children represent fewer than 5% of all pediatric brain tumors. Several benign tumors are cured with complete resection, including intraparenchymal schwannomas.^{162,163} Metastasis rarely occurs in children but has been reported in patients with sarcomas (e.g., Ewing sarcoma, osteogenic sarcoma), germ cell tumors, neuroblastoma, and Wilms

tumor.^{164,165} The adult experience suggests that resection of accessible lesions followed by adjunctive therapy prolongs survival. Primary central nervous system lymphomas are very rare in children, can be located within the cerebral hemispheres, and may be associated with prior cranial radiation, as some patients are long-term survivors of childhood leukemia.^{166,167}

Pearls

- These tumors are relatively rare, and thus, one should review the relevant literature before deciding on a treatment plan.
- With the exception of germinomas and nongerminomatous germ cell tumors, maximal cytoreductive surgery is the primary mode of treatment for these tumors.
- Like medulloblastomas, supratentorial PNETs require multimodal therapy, but they have a worse prognosis.
- DNETs and gangliogliomas should be resected in patients with medically intractable epilepsy. Areas of cortical dysplasia can be present within, or adjacent to, these tumors. Patients with long-standing seizures (i.e., longer than 1 year) may require a more extensive preoperative work-up of their seizures and intraoperative ECoG because resection beyond the actual lesion may be needed to control seizures.
- Although often massive at presentation, DIGs can usually be safely resected.
- Patients with gangliogliomas, DNETs, DIGs, and meningiomas rarely need adjuvant therapy—even when residual tumor is present—but do require long-term clinical and radiologic follow-up. Re-resection in patients with recurrent or progressive disease is usually the best therapy.
- The extent of resection is the most important prognostic factor for supratentorial PNETs and CPCs in patients presenting without metastatic disease. Residual tumor warrants a second resection.
- Measures to minimize blood loss during the resection of CPTs can be taken preoperatively (i.e., with embolization or neoadjuvant chemotherapy) and intraoperatively (by eliminating the main vascular pedicle).

36 Optic Pathway Gliomas

Ben Shofty, Liat Ben-Sira, Anat Kesler, and Shlomi Constantini

Optic pathway gliomas (OPGs) are one of the most challenging neoplasms in modern pediatric neuro-oncology. Recent advances in imaging, surgery, and chemotherapy may lead to a better understanding of the pathophysiology and better clinical results. This chapter reviews these advances and the current treatment paradigms.

36.1 Definition and Classification

The term *optic pathway glioma* is used to define low-grade glial neoplasms that are epicentered within the visual system: the optic nerve (ON), optic chiasm, optic tracts, and, rarely, the optic radiations. The various presentations of OPG are illustrated in ► Fig. 36.1. These lesions tend to have an erratic natural history, and they require careful follow-up and management by a multidisciplinary team. The subset of patients seen by pediatric

neurosurgeons may be biased toward the aggressive end of the spectrum, with tumors that have a tendency to progress and require multiple treatment lines.

OPGs comprise a wide spectrum of anatomical variations. In addition, age, the coexistence of neurofibromatosis type 1 (NF-1), histology, and molecular markers may be important factors in the clinical behavior of OPGs and in the practical process of individualized decision making regarding their treatment.

Several different methods have been developed for the classification of OPGs. Dodge et al introduced the first of these in 1958.¹ The Dodge system classifies OPGs into three groups based on the anatomical location of the tumor (► Fig. 36.2). Tumors of the ON are Dodge I, tumors of the chiasm are Dodge II, and posterior tumors, or those that extend into nearby structures, are Dodge III. This method, defined in the era before computed tomography (CT) and magnetic resonance (MR)

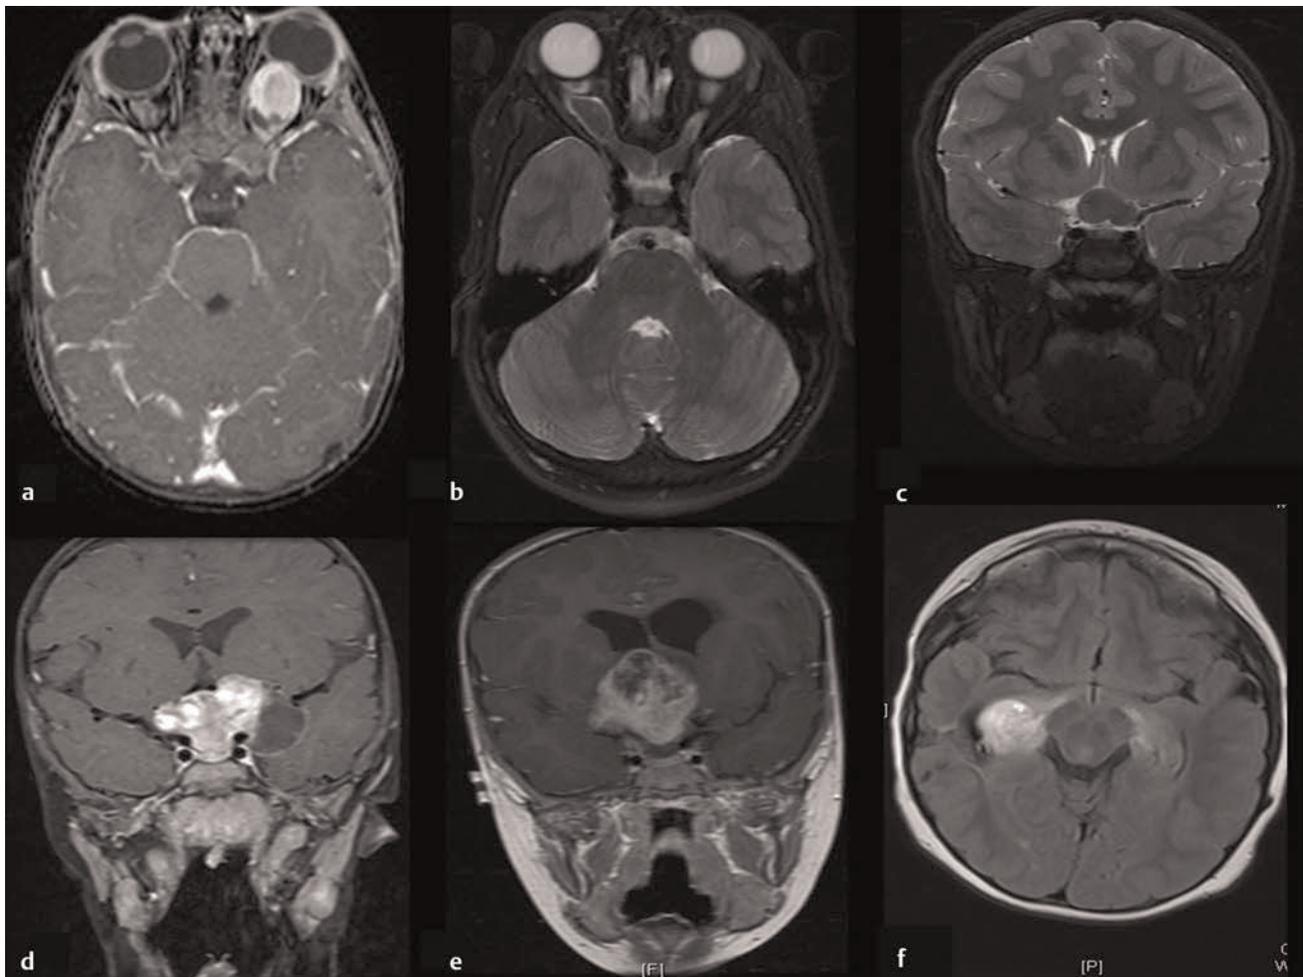

Fig. 36.1 Various presentations of optic pathway glioma. (a) Isolated optic nerve (ON) glioma of the left ON. (b) Bilateral ON glioma involving the chiasm. (c) Chiasmal glioma with no involvement of the hypothalamus. (d) Large chiasmal glioma involving the hypothalamus with a cystic component. (e) Large chiasmatic/hypothalamic glioma that compresses the third ventricle, causing hydrocephalus. (f) Posterior glioma of the optic radiations.

imaging, is still widely used, mainly for research purposes. However, its clinical relevance is limited.

The *modified Dodge* classification system, developed in 2008,² is a more detailed anatomical classification that breaks down each component into several highly precise categories. The modified Dodge system also takes into account additional factors, such as the existence of NF or leptomeningeal dissemination.² This method, although very precise anatomically, is probably too complicated to be routinely implemented in clinical patient care. Another drawback of both Dodge classification methods is the lack of sensitivity to indicate tumor progression.

A third classification system that attempted to address the issue of functional status was suggested by McCullough and Epstein in 1985.³ This classification system consists of two components, tumor/anatomical and functional. The *tumor component* is divided into four classes (T1, one ON; T2, both ONs; T3, optic chiasm; T4, hypothalamus/thalamus). The *functional component* is divided into five classes (V0, normal; V1, impaired, one eye; V2, impaired, both eyes or blind, one eye; V3, blind, one eye and impaired, one eye or field defect; V4, blind, both eyes). We recently suggested a new morphological classification that utilizes recent advances in imaging and may aid in clinical management and patient stratification (► Table 36.1, ► Fig. 36.3).

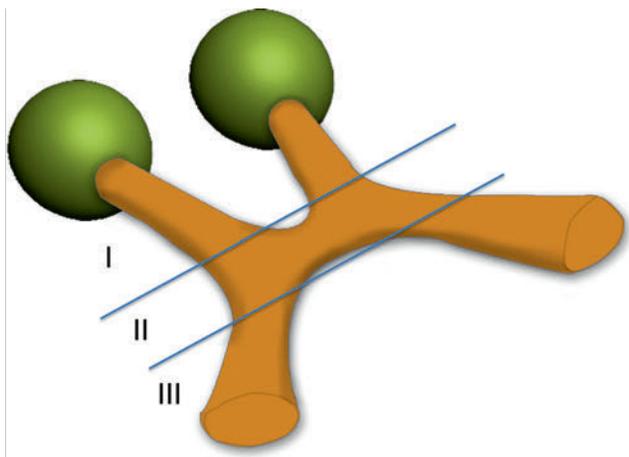

Fig. 36.2 Schematic representation of the 1958 Dodge classification system. I, optic nerve glioma; II, chiasmatic glioma; III, posterior glioma or chiasmatic with involvement of extraoptic structures.

Other factors that should be considered in an attempt to stage an OPG are the presence of NF-1, the age at diagnosis, the symptoms at presentation, and the risk for hydrocephalus.

Caution is warranted when attempts are made to classify OPGs in patients with NF-1. Despite the fact that this is a relatively common tumor in patients with NF-1, many radiologic abnormalities may complicate the diagnosis. An example of such misleading abnormalities are T2 hyperintensities that sometimes have mass effect, and focal signal changes within the ON that may be either preneoplastic or without any significance.

36.2 Epidemiology

OPGs are the most common primary neoplasms of the neural visual pathways, comprising approximately 1% of all central nervous system (CNS) neoplasms in the general population and approximately 5% of CNS neoplasms in children.⁴ The annual incidence (as reported in the pre-MR imaging era) is 1 per 100,000.⁵ The real number is probably higher. Of all patients with this diagnosis, 80% are in the first decade of life, and 90% are in the first two decades. The mean age at diagnosis is 8.8 years in older series and ranges between 2.7 and 5.4 years in more recent series.⁶⁻⁸ An estimated 37% of OPGs tend to progress.⁹ There is no gender predisposition. In a large series published by Nicolin et al, 58% of 133 patients with OPG were positive for NF-1. The mean age at diagnosis in this series was 5.9 years, 50% of the tumors were hypothalamic/chiasmatic, 60% were diagnosed by imaging only, and 52% required treatment over the course of a follow-up period of 9 years.¹⁰ The high proportion of Dodge II or III tumors in this series may be attributable to a referral bias.

36.3 Optic Pathway Glioma and Neurofibromatosis Type 1

OPGs are one of the diagnostic criteria for NF-1, and bilateral OPGs are considered pathognomonic for NF-1. With regard to outcome, the simultaneous occurrence of the two diseases is considered a good prognostic factor.^{9,11} In a series comparing OPGs associated with NF-1 and sporadic gliomas, the children with NF-1 had a significantly better clinical picture at diagnosis, with less increase in intracranial pressure, less decrease in visual acuity, and fewer abnormalities of the fundus of the eye.

Table 36.1 Morphological classification of optic pathway glioma

Nerve	Chiasm	Posterior	General
1. Mild thickening	1. Confined to chiasm	1. Focal involvement	Cyst: yes/no
2. Severe thickening	2. Chiasm and hypothalamus	2. Extensive involvement	Hydrocephalus: yes/no
Enlarged ONSD: yes/no	3. Chiasm and third ventricle		Other CNS malignancies: yes/no
Tortuous ON: yes/no	4. Major suprasellar involvement		Diffuse NF-related changes: yes/no
Pressure on globe: yes/no			Age at presentation?
Enhancement: yes/no	Enhancement: yes/no	Enhancement: yes/no	Favorable molecular properties?
Isolated involvement: yes/no	Isolated involvement: yes/no	Isolated involvement: yes/no	

Abbreviations: CNS, central nervous system; ONSD, optic nerve sheath diameter; NF, neurofibromatosis.

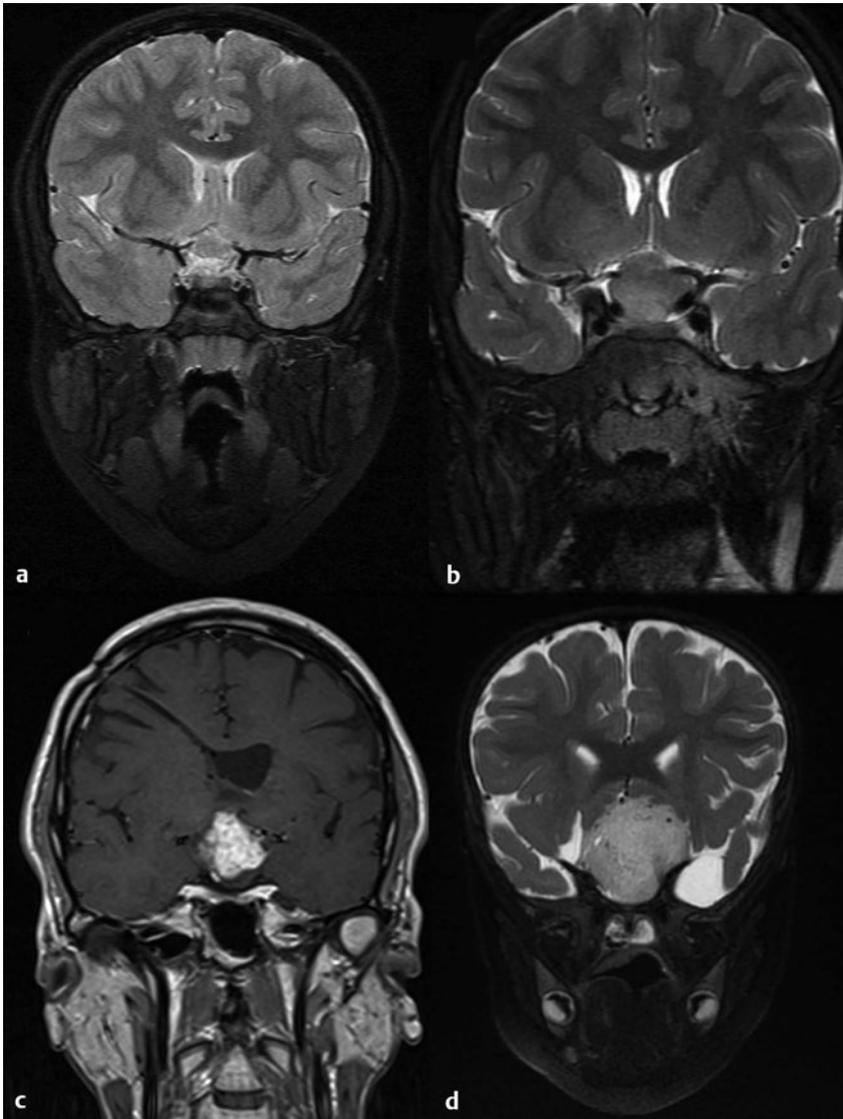

Fig. 36.3 Four different classes of chiasmatic/hypothalamic glioma. (a) Chiasmatic thickening only. (b) Chiasm and hypothalamus. (c) Chiasm and third ventricle involvement. (d) Major supra-sellar involvement.

Radiologic progression, visual deterioration, and endocrine damage were also less frequent in children with OPGs associated with NF-1.

OPGs appear in almost 30% of patients with NF-1 and may present with a variety of radiologic and clinical changes.¹² In patients with NF-1, the lesion is more likely to be located anteriorly and involve a single nerve than in patients with generic OPG.¹³ The spectrum of imaging appearances in patients with NF-1 is broad, ranging from fine signal changes on T2-weighted MR images, to an enlarged ON sheath, to gross ON tumors and chiasmatic lesions that protrude into the third ventricle or other neighboring structures. When posterior tumors are being considered in patients with NF-1, it is important to remember that they may easily be confused with NF-related T2 hyperintensities that may be expansile and have a mass effect. A careful radiologic and clinical follow-up is warranted before any therapeutic decisions are made for lesions of the optic radiations. Historically, NF-1 OPGs were considered to be relatively indolent tumors that did not tend to progress. Recently, several

publications have described a more active clinical course, with progression of the tumor noted in up to 75% of patients with NF-1, even in children older than 11 years.¹⁴ Recently, macrocephaly has also been correlated with OPG in patients with NF-1.¹⁵

36.4 Clinical Presentation

Visual complaints such as decreased visual acuity, nystagmus, and proptosis are found at presentation in 46% of patients. Neurologic problems such as headaches, vomiting, and seizures are present in 16% of patients.¹⁰ These low percentages are attributed to the young patient age and the high percentage of patients whose tumors are diagnosed during routine screenings, especially patients with NF-1. The age at diagnosis of patients with generic OPGs is older than that of patients with NF-1. This is mainly attributed to the fact that a diagnosis is made only after clinical symptoms appear, not during routine screening, as in patients with NF-1.⁸

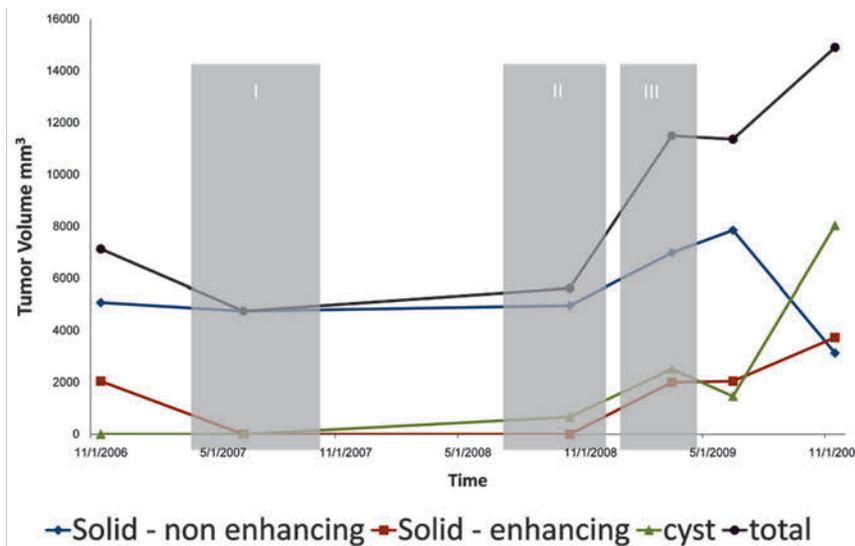

Fig. 36.4 Volumetric follow-up of one of our patients with internal segmentation into three components and integrated treatment periods. Note that despite the fact that the gross total tumor volume enlarges, there is a marked reduction of the solid component following chemotherapy. The main progression is of the cystic component. Total, gross total volume of the tumor; Solid-enhancing, volume of the enhancement-receiving bulk on magnetic resonance (MR) imaging; Solid-nonenhancing, volume of the solid portion of the tumor that does not receive contrast enhancement on MR imaging; Cyst, volume of the cystic component on MR imaging. I, treatment period with vincristine and carboplatin; II, treatment period with vinblastine; III, treatment period with rapamycin and erlotinib (Tarceva; Genentech, South San Francisco, CA).

The mode of presentation varies with the anatomical location of the tumor. Posterior tumors are associated with evidence of endocrine dysfunction, such as precocious puberty, and with hydrocephalus. Anterior tumors are associated more with visual abnormalities.¹⁶ Visual signs such as palsies of cranial nerves III, IV, and VI, papilledema, and optic atrophy are present in a minority of cases. The type of visual deficit usually correlates with the tumor location; posterior tumors may cause hemianopia, whereas unilateral ON tumors will cause monocular visual impairment. Signs and symptoms of raised intracranial pressure should be taken seriously because acute hydrocephalus has been reported as a presenting symptom. Diencephalic syndrome (cachexia, macrocephaly, nystagmus, and visual deficit) is seen in 21% of infants with chiasmatic/hypothalamic tumors.¹⁷

36.5 Diagnostic Studies

36.5.1 Radiology

MR imaging is the gold standard for the diagnosis of OPG. To maximize the diagnostic yield, MR protocols should be planned with the assistance of an experienced neuroradiologist and should include orbit-directed scanning with fat suppression and contrast injection. Tractography may prove beneficial in the future but so far remains experimental.¹⁸

Tumors may differ in MR appearance depending on their location, but they are usually isointense on T1 and hyperintense on T2, receive variable enhancement, and have cystic as well as solid nonenhancing components. Tumors of the ON usually do not have cystic changes, appearing as gross thickening of the nerve itself, with or without nerve sheath enlargement. The differential diagnosis for ON enlargement is broad and includes meningioma, neuroma, hemangioblastoma, and lymphoma.¹⁹ ON sheath enlargement is found in nonneoplastic conditions such as increased intracranial pressure, optic neuritis, Graves disease, sarcoidosis, toxoplasmosis, central vein occlusion, idiopathic intracranial hypertension, and tuberculosis.^{20,21} Posterior tumors may appear as minimal chiasm thickening, or as large

masses protruding into the third ventricle with apparent mass effect. Cystic changes are common and are a part of the natural history of the tumor. Neoplastic changes posterior to the lateral geniculate nucleus are rare and are difficult to differentiate from NF-1 T2 hyperintensities. Unfortunately, the initial radiologic appearance does not correlate with the visual prognosis. We have found deteriorating vision in patients with tumors that seem to be stable anatomically, as well as stable vision in patients whose tumors demonstrated structural progression. It has been suggested that dynamic contrast enhancement may correlate with progression, with larger mean permeability values in aggressive tumors.²²

Because of the long follow-up required in these patients and the importance of the early detection of changes in the tumor bulk or in its internal components, we recommend the use of volumetric assessments. These measurements, although time-consuming, may improve patient care by enabling more accurate decision making.^{23,24} ▶ Fig. 36.4 demonstrates a volumetric follow-up of one of our patients; the corresponding MR images are presented in ▶ Fig. 36.5.

36.5.2 Ophthalmology

Neuro-ophthalmology examination is crucial for both the diagnosis and follow-up of OPG, as visual decline is a worrisome consequence of the tumor. The neuro-ophthalmologic evaluation is often difficult, especially in young patients whose cooperation is limited. A decline in visual acuity is often present at diagnosis and sometimes may be the reason for initial testing, even in the very young (e.g., an infant who starts bumping into objects or sitting closer to the television). In addition, color vision, visual field, eye movements, relative afferent pupillary defect, pupil size, and the fundus should all be evaluated. Any progressive change should be considered seriously as a reason to initiate therapy. In very young children, a normal examination does not rule out visual impairment from an OPG. Recently, the use of optical coherence tomography (OCT) was shown to detect loss of the retinal nerve fiber layer in children with OPG (▶ Fig. 36.6). This may prove to be an auxiliary

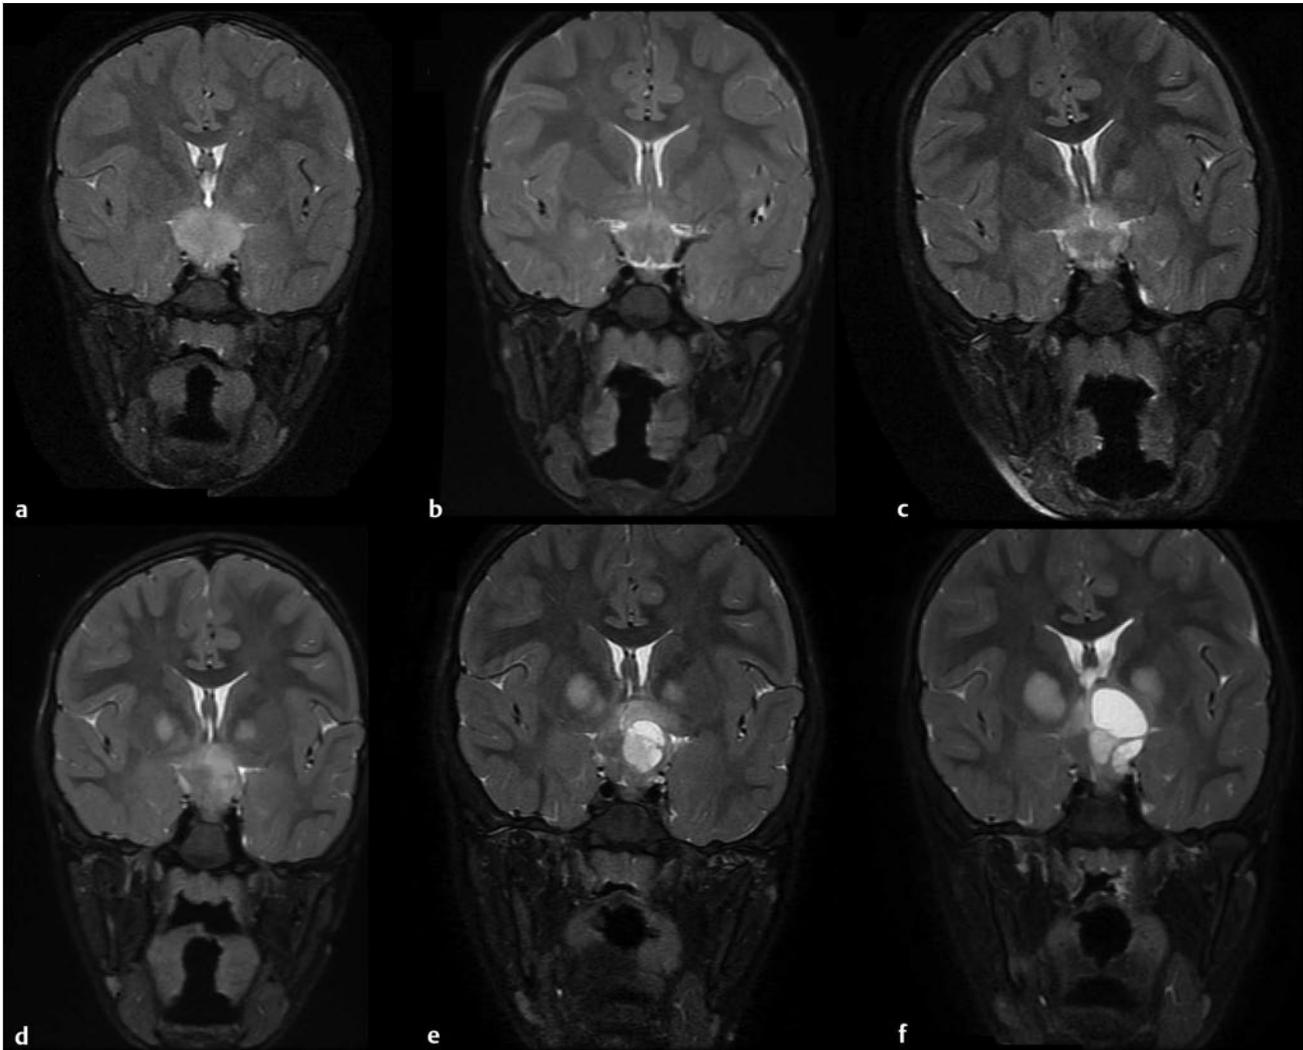

Fig. 36.5 Anatomical history of a chiasmatic/hypothalamic glioma. (a-f) Serial coronal T2 images of a 4-year-old boy with neurofibromatosis type 1 who presented with visual deterioration. Within 4 years, a deterioration to bilateral blindness occurred despite three different chemotherapy treatment lines. (e,f) Note the cystic changes that the tumor undergoes.

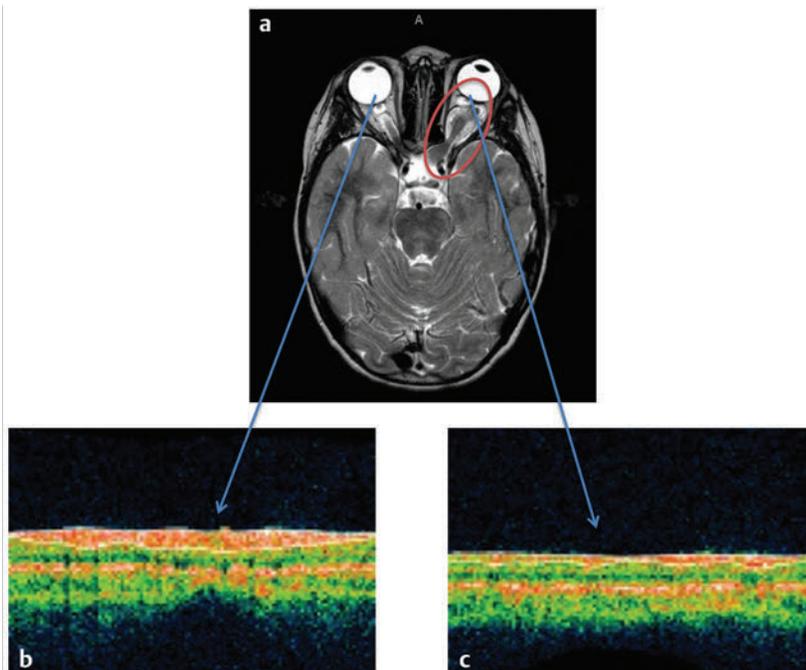

Fig. 36.6 Patient with neurofibromatosis type 1 and optic pathway glioma (a) with a tumor on the left optic nerve (red circle). Optical coherence tomography of the right, normal eye (b) and of the left, tumor-affected eye (c) (blue arrows). This patient had a visual acuity of 20/20 in the unaffected (right) eye and of 20/400 in the tumor-affected eye. Visual acuity correlated well with retinal nerve fiber layer thickness of 105 μm on the right (normal) versus 48 μm on the left (severely thinned). (Images courtesy of Dr. Robert Avery, Children's National Hospital, Washington, DC.)

tool in diagnosing visual damage in young children, as well as in providing evidence regarding visual reserve and the need for treatment.^{25,26}

36.5.3 Endocrine Assessment

An endocrine assessment should be done in any child with chiasmatic/hypothalamic glioma. Endocrine abnormalities such as central precocious puberty and growth hormone deficiency are detected in approximately 20% of patients with an OPG. It should be noted that growth hormone deficiency is present in approximately 2.5% of patients with NF-1, even those without OPG.²⁷

36.6 Pathology

OPGs are typically low-grade glial neoplasms. Pilocytic astrocytoma accounts for the vast majority of these tumors. The rest usually consist of fibrillary and pilomyxoid astrocytomas, oligodendrogliomas, and gangliogliomas. A more aggressive behavior pattern may be predicted with labeling indices such as high Ki-67^{4,28} as well as pilomyxoid histology.^{29,30} Malignant transformation is rarely seen and is most frequently associated with irradiation.³¹

36.7 Natural History and Prognosis

OPGs have an erratic natural history. Some of these tumors progress, others are steady for a lifetime, and others spontaneously regress.^{32,33} This has led to the theory that OPGs are not a single entity, but rather a group composed of two or even three subtypes that are often hard to distinguish from one another. These subtypes vary widely in their clinical and radiologic outcomes. Although some OPGs undergo spontaneous regression, a significant group of large chiasmatic/hypothalamic tumors tend to progress and even metastasize. ▶ Fig. 36.4 demonstrates a progressive OPG of the chiasmatic/hypothalamic type over 4 years of follow-up. Interestingly, of the 5% of low-grade gliomas that undergo leptomeningeal spread, OPGs account for approximately 50%.³⁴ Before this behavior pattern was recognized, these tumors were sometimes considered benign, even hamartomatous in nature,³⁵ requiring only careful follow-up; however, they are now perceived as progression-prone, persistent tumors that pose a major therapeutic dilemma. As many as 35% require treatment at presentation.¹⁰

Patients who do not require treatment at initial presentation have varying chances for progression. In those with NF-1, the likelihood of progression is 15%, whereas in patients with sporadic OPGs, the probability of progression is 75%.

Molecular analysis of tumor tissue has shown promising early results in predicting the course of the disease. In particular, the BRAF-KIAA 1549 fusion protein seems to indicate tumors with a tendency to arrested growth and even to spontaneous senescence. In a recent study, the 5-year progression-free survival (PFS) rate was 61% ± 8% for B-K fusion protein–positive patients and 18% for B-K fusion protein–negative patients. In this study, 61% of sporadic OPGs were positive for fusion

protein, and no OPG related to NF-1 was positive for this mutation.³⁶ Although not currently utilized in routine clinical practice, we believe that this analysis should be considered for any patient without NF-1 for whom therapeutic decisions are being made based on radiologic progression only.

36.8 Treatment

The follow-up and management of OPG require an experienced multidisciplinary team that provides individualized patient care. Only then can adequate therapeutic decisions be made. The goal of treatment is to prevent visual decline and to achieve long-term tumor control. In the presence of a severe mass effect or hydrocephalus, immediate, life-saving neurosurgical procedures may be indicated. In most cases, however, OPGs are not life-threatening tumors. The risk-to-benefit ratio of treatment must therefore be considered carefully for each patient.

The exact timing of treatment initiation is one of the major open questions in OPG management. In most cases, we recommend delaying treatment for as long as possible unless a clear radiologic progression or visual decline is noted. Treating an asymptomatic or minimally symptomatic stable patient seems to offer no advantage over observation alone.^{6,28,37} Thus, current guidelines suggest intervention *only* when there is a documented decline in vision or radiologic progression.⁹ Treatment initiation dilemmas may be very relevant in a child, especially an infant, who presents for the first time with compromised vision. At this moment, progression cannot be defined; however, compromised reserve may be a relevant reason to start treatment earlier rather than later.

We recommend imaging and neuro-ophthalmologic examinations (including visual field and OCT if available) every 6 months. Patients with compromised reserve for whom a decision has been made not to treat should be clinically examined more frequently. If the tumor is chiasmatic/hypothalamic, a detailed endocrinologic evaluation should be performed. If the patient has been stable for a period of a year and has no adverse prognostic factors, follow-up visits may be scheduled on a yearly basis.

The choice between treatment options such as surgery, chemotherapy, and irradiation is not easy and depends on the team's experience and biases. The following sections outline general rules for these treatment modalities. ▶ Fig. 36.7 illustrates a suggested management algorithm for OPG.

36.8.1 Biopsy

For tumors with a characteristic MR imaging appearance that are epicentered on the optic pathway, especially in a patient with NF-1, no biopsy is required.³⁸ Biopsies are indicated if the tumor has an atypical appearance on MR imaging, if the age of the patient is unusual (older than 10 years or younger than 1 year), or if the patient has unusual clinical characteristics (rapidly progressing or severe neurologic deficits other than vision loss). It has been argued that the mere knowledge that an OPG has pilomyxoid characteristics is important for early treatment decisions. The value of biopsy of an OPG for molecular diagnosis is still controversial. The example of the *BRAF* mutation, provided previously, may represent only the beginning of a

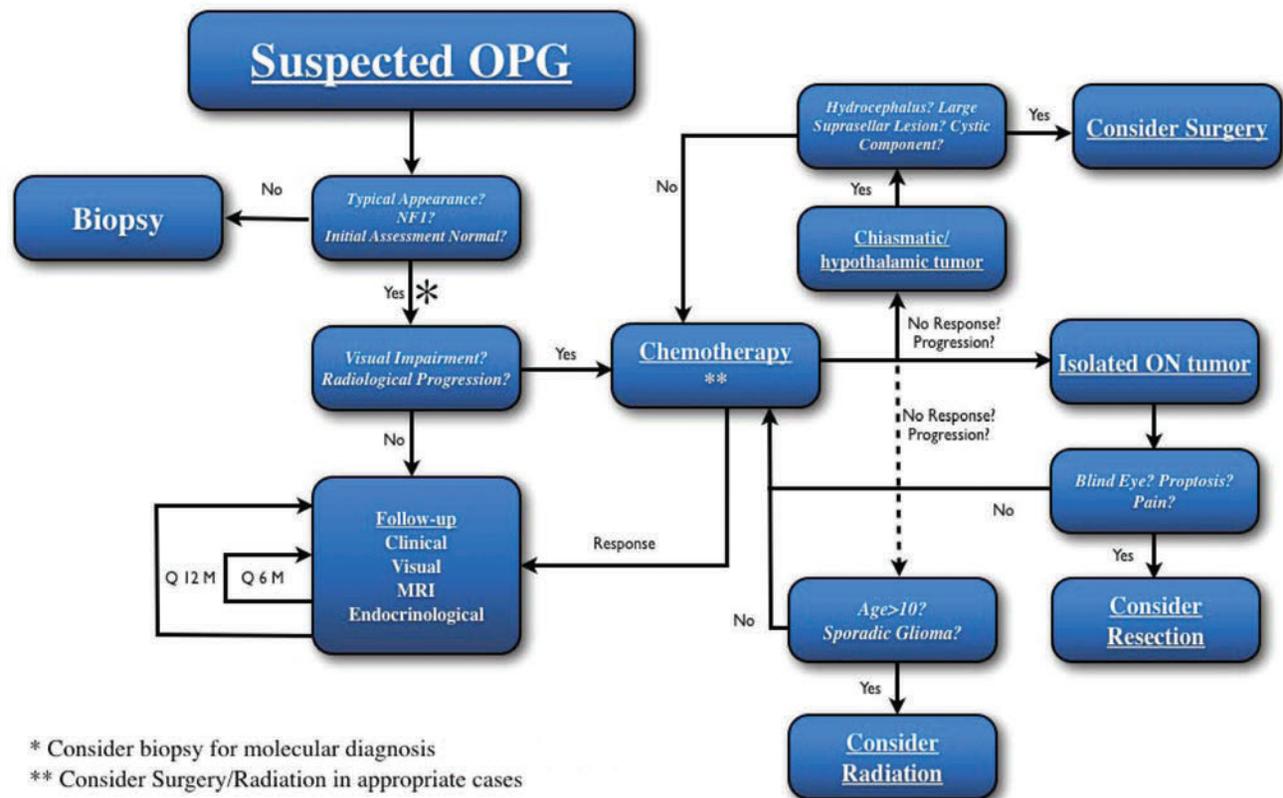

Fig. 36.7 Management algorithm for patients with optic pathway glioma. MRI, magnetic resonance imaging; ON, optic nerve; OPG, optic pathway glioma. See text for specifics.

long-awaited breakthrough. Biopsies may be useful for the molecular diagnosis of tumor characteristics that may have prognostic or therapeutic consequences.^{36,39,40} These analyses, although not yet included in routine clinical practice, are proving valuable, and we expect them to be essential for making therapeutic decisions and estimating prognosis in the near future.

36.8.2 Surgery

Clinical series describing surgical results for OPG usually comprise small numbers of patients, with vague inclusion criteria, no control groups, and poor follow-up. The current situation includes wide variations between different centers and groups with regard to the threshold for open surgery.

Tumors confined to the ON are considered for resection if the patient has progressive proptosis or intractable pain in a blind eye. These tumors can be approached via unilateral frontal craniotomy and orbitotomy or through the eye, especially when enucleation of the entire eye is warranted. Globe-sparing resection is also possible. It should be noted that sectioning the nerve close to the chiasm risks damage to the advancing nasal fibers (Wilbrand's knee) from the contralateral eye.

The surgical management of chiasmatic/hypothalamic tumors is even more controversial. Radical resection in a patient with viable eyesight is usually not recommended because of the susceptibility of the surrounding neural structures (hypothalamus and brainstem). In addition, there is a high risk for damage

to the optic apparatus. Subtotal resection of tumors that grow outside the visual system, such as in the third ventricle or the anterior and lateral subarachnoid spaces, can be performed for a subset of large suprasellar lesions.⁴¹ Chiasmatic/hypothalamic lesions may be approached via interhemispheric transcallosal, subfrontal pterional, subtemporal, or bifrontal interhemispheric translamina terminalis routes, depending on the direction and extent of the tumor. Combination approaches may also be used for more extensive lesions. Image guidance facilitates accurate navigation and the avoidance of damage to critical structures. Hydrocephalus may respond to decompression alone but may also require shunt placement in many cases. Ascites secondary to ventriculoperitoneal shunting in patients with chiasmatic tumors is common and may require diversion of the CSF to the atrium rather than to the abdomen.⁴² Large cystic components containing mucinous fluid are common and may require multiple resections and drainage procedures. Shunts placed within these cysts tend to malfunction after a short period of time; Ommaya reservoirs may be used in these situations for intermittent tapping and drainage.

36.8.3 Chemotherapy

Chemotherapy is considered the first line of treatment in most cases of children with progressive OPG.

"Gentle chemotherapy" with vincristine and carboplatin was introduced in 1988 by Packer et al and is now an accepted

first-line treatment.⁴³ This regimen reported PFS rates of 75% at 2 years and 68% at 3 years for chiasmatic tumors.⁴³ Carboplatin alone may also be effective in OPG treatment, with a short-term PFS rate of 83% and disease stabilization in 85%.⁴⁴ Weekly vinblastine is also frequently used as a first-line treatment or in patients with carboplatin allergies.⁴⁵ A new protocol of bevacizumab and irinotecan has shown preliminary effectiveness in the treatment of recurrent low-grade gliomas.⁴⁶ Mammalian target of rapamycin (mTOR) is an important part of the Ras pathway, which is hyperactivated in NF-1 and is considered a potential target for inhibition. So far, protocols that include mTOR inhibitors, such as a recent erlotinib (Tarceva; Genentech, South San Francisco, CA) and rapamycin protocol, have been only mildly effective.⁴⁷ Clinical trials with other mTOR inhibitors such as RAD001 (everolimus) are ongoing.

Several papers published in recent years have shown disappointing results for visual outcome following chemotherapy for OPGs.^{48–50} In many patients, despite some success in achieving structural tumor control, there was no improvement and even further decline in visual ability. Others, such as Fisher et al, have provided somewhat better results for visual prognosis with chemotherapy treatment, but for a relatively short follow-up time, providing results only after first-line chemotherapy and only for patients with NF-1.⁵¹

In addition to anatomical tumor response, chemotherapy has shown benefits in preserving intellectual function in comparison with radiation, and in controlling diencephalic syndrome.^{52,53}

36.8.4 Radiation

With the establishment of chemotherapy as the first-line treatment of choice for low-grade gliomas in general, and for OPGs specifically, the use of radiation has lessened significantly. The long-term negative consequences of radiation, especially in young patients and even more so in patients with NF-1, have made radiation an alternative used only as a last resort.

In children younger than 3 years old, radiation is contraindicated because of unacceptable cognitive impairment. In older children without NF-1, radiation may be effective for OPGs that are progressive despite chemotherapy, for metastatic tumors, or for unresectable tumors. With the usual dose of 45 to 60 Gy in 1.6- to 2-Gy fractions, 5-year PFS and overall survival rates are reported to be in the range of 82 to 85% and 93 to 94%, respectively.⁵⁴ A modest beneficial effect on visual ability was also reported.^{55,56}

The main reason for discouraging radiation therapy for OPG is its multiple long-term adverse effects. These are especially apparent in the NF-1 population. In the generic OPG population, even children older than 3 years who received radiation therapy experienced cognitive side effects.⁵⁷ Endocrine dysfunction occurs in 39 to 55% of patients treated with irradiation.^{55,57–59} In a large series of 69 patients treated before the chemotherapy era, published by Cappelli et al in 1998, approximately 15% of patients treated with irradiation had cerebrovascular complications. In the same series, approximately 30% of patients treated with irradiation at a young age had severe intellectual disabilities.⁵⁶ In the NF-1 population, the two main long-term effects of radiation are moyamoya syndrome⁶⁰ and secondary CNS malignancies. In a series of 28 patients treated

with irradiation described by Kestle et al, 5 (18%) developed moyamoya syndrome. In this same series, 60% of patients with NF-1 developed moyamoya syndrome.⁶¹ Secondary malignancies (such as malignant peripheral nerve sheath tumors) occur in 50% of patients with OPG and NF-1 who receive irradiation, as opposed to 20% of patients who do not receive irradiation. There is an increased relative risk (threefold) for the NF-1 OPG group treated with irradiation.⁶² In addition, irradiation tends to induce anaplastic changes in the original glial tumor. In one series dealing with low-grade gliomas, 16% of patients treated with irradiation developed anaplastic changes, as opposed to none in the group that did not receive radiation.⁶³

Stereotactic radiosurgery has been tested as a possible treatment for OPG, with some promising results. In several small series, good tumor control was achieved, improvement in vision was noted, and side effects were rather small.^{64,65} Some of the serious adverse effects associated with radiation may be technique-dependent, and the further examination of newer, safer techniques is warranted, especially when the rather low efficacy of chemotherapy in improving and preserving visual ability is considered. Gamma knife and proton beam therapy may also prove to be useful tools in the future.^{66–68}

36.9 Outcome

OPG outcome is generally favorable. Long-term survival rates are excellent, ranging from 80 to 96% in numerous series over the last 10 years.^{10,16,28} In an older series from 1993, the overall 10-year survival rate was 84%, with anterior tumors (nerve and chiasm) having a 10-year survival of 95% and posterior tumors a 10-year survival of 76%.⁶⁹ PFS rates vary and are considered to be about 50% depending on location, background, and the need for treatment. In the same series from 1993, PFS at 10 years was 80% for tumors of the nerve and chiasm and 59% for tumors spreading outside the chiasm.⁶⁹

From our own experience, approximately 25% of patients with OPG referred to a tertiary center require therapy; of this group, approximately 75% will need to receive second-line treatment.⁴⁸ These numbers, higher than accepted numbers in the literature, are biased because of the more aggressive nature of the tumors seen by a pediatric neurosurgeon. Various factors described in the literature as having an effect on prognosis⁷⁰ are summarized in ► Fig. 36.8.

Because of the big difference between long-term survival and PFS, as well as the heterogeneity of the patients, the long-term follow-up of patients with OPG is necessary. In addition, the discrepancy between functional outcome and anatomical outcome makes prospectively estimating the outcome of an individual patient with OPG even more difficult.

36.10 Conclusion

The goal of visual control in OPG has not yet been reached. Further understanding of the different OPG subgroups and the underlying pathophysiology of visual loss is required to treat these patients effectively and individually. Large multicenter prospective studies aimed at examining new treatment modalities are desperately needed to improve this front.

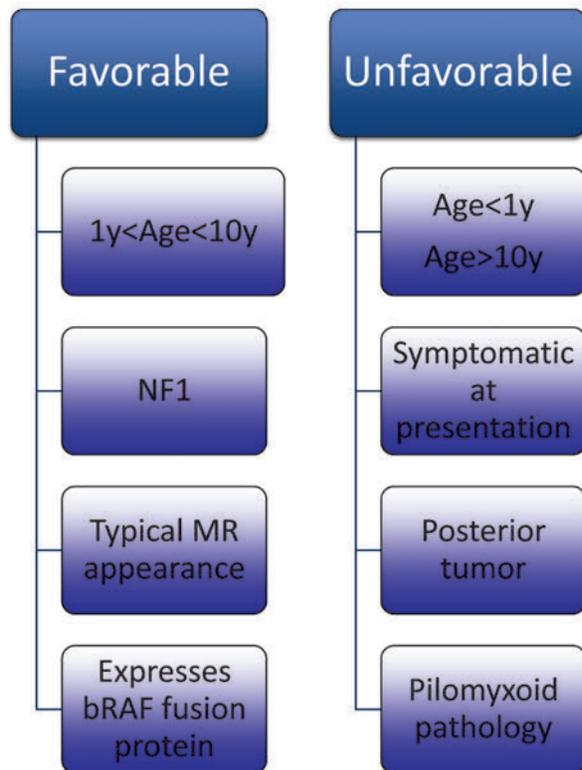

Fig. 36.8 Favorable versus unfavorable prognostic factors.

Pearls

- Bilateral optic nerve gliomas are pathognomonic for NF-1.
- Careful and close radiologic and clinical follow-up is the recommended initial approach for neurologically intact patients.
- Consider obtaining tissue for molecular analysis in selected cases.
- Treatment is usually indicated only when clear radiologic or visual progression is documented.
- The initial treatment of choice is chemotherapy.
- Surgery is reserved for orbital tumors in the setting of a blind or proptotic eye and for exophytic chiasmatic/hypothalamic tumors that cause mass effect or hydrocephalus or have a large cystic component.
- Radiation should be avoided in patients with NF-1. For sporadic OPGs, radiation can be selectively used in children older than 10 years or if chemotherapy fails to control tumor growth.

36.11 Acknowledgment

The previous version of this chapter by Cian James O'Kelly and James T. Rutka served as a basis for this version. We thank them for their contribution.

37 Craniopharyngiomas

Jeffrey H. Wisoff and Bernadine Donahue

Cushing graphically described craniopharyngiomas as “the kaleidoscopic tumors, solid and cystic which take their origin from epithelial rests ascribable to an imperfect closure of the hypophyseal or craniopharyngeal duct” and whose management is “one of the most baffling problems to the neurosurgeon.”¹ The benign histology of these tumors is often in marked contrast to their malignant clinical course in children. The location of craniopharyngiomas, which have an intimate association with the visual pathways, hypothalamus, and limbic system, predisposes patients with these tumors to severe visual, endocrine, and cognitive deficits, both at presentation and as a result of treatment. Although most children can compensate for neurologic deficits and endocrinologic deficiencies, the cognitive and psychosocial sequelae may be functionally devastating, interfering with education, limiting independence, and adversely affecting the quality of life as the children approach adulthood.²

37.1 Epidemiology

Craniopharyngiomas constitute approximately 3% of all intracranial neoplasms.^{3,4} They are the most common nonglial tumor of childhood, accounting for 6 to 9% of pediatric brain tumors.⁵⁻⁷ Although craniopharyngiomas comprise a significant proportion of pediatric brain tumors, on a population basis they are rare. Based on an analysis of three population-based cancer registries, the incidence of craniopharyngioma in the United States is between 0.13 per 100,000 and 0.18 per 100,000 per person-years.⁸ A bimodal distribution by age has been noted, with peak incidence rates in children and among older adults. Among children, the incidence is greatest between the ages of 6 and 10 years, followed by the ages of 11 and 15 years.^{8,9} From 33 to 54% of all craniopharyngiomas occur in the pediatric age group,^{6,8,10-14} with approximately 96 to 145 new cases annually occurring in children from 0 to 14 years of age.

Although there does not appear to be any racial or ethnic predilection for craniopharyngiomas, the influence of gender is unclear. After all the data are considered, craniopharyngioma may occur slightly more often in boys.^{8,13,15-17}

Stiller and Nectoux¹⁸ have reported that the proportion of brain tumors that are craniopharyngiomas varied substantially among different global regions: 1.5% in Australia, 4.7 to 7.9% in Europe, 3.9% in Japan, 2.7% (Caucasians) and 4.9% (African Americans) in the United States, and 11.6% in Africa. Although this international variation in occurrence has led to speculation regarding environmental influences, the data must be interpreted with caution because socioeconomic conditions preclude the population-based reporting of all brain tumors in developing countries.

37.2 Pathology

Craniopharyngiomas develop from epithelial nests that are embryonic remnants of the Rathke pouch located on an axis extending from the sella turcica along the pituitary stalk to the

hypothalamus and floor of the third ventricle.^{4,19} Craniopharyngiomas gradually enlarge as partially calcified solid and cystic masses predominantly in the suprasellar region, and the cystic component can reach several centimeters. They extend along the path of least resistance into the basal cisterns or can invaginate the third ventricle. With continued growth superiorly into the third ventricle, hydrocephalus may develop.

Craniopharyngiomas have two basic patterns of cellular growth: adamantinomatous and papillary.^{3,4,10,14,20,21} Mixed tumors with both adamantinomatous and squamous papillary components or combinations of craniopharyngioma and Rathke cleft cysts can occur.^{3,4,10,14,20-23}

The adamantinomatous tumors are the most common variant, occurring at all ages. They resemble the epithelium of tooth-forming tumors, containing three distinct components: a basal layer of small cells; an intermediate layer of variable thickness with loose, stellate cells; and a top layer facing the cyst lumen, where the cells are abruptly enlarged, flattened, and keratinized. At the cyst surface, desquamated epithelial cells are present either singly or in characteristic stacked clusters (keratin nodules). These nodules may undergo mineralization with the accumulation of calcium salts, which in rare instances progresses to metaplastic bone formation. The cysts in adamantinomatous craniopharyngiomas usually contain an oily liquid composed of this desquamated epithelium, which is rich in cholesterol, keratin, and occasionally calcium.

Squamous papillary craniopharyngiomas occur nearly exclusively in adults and tend to involve the third ventricle.²⁴ They consist of solid epithelium, without loose stellate zones, in a papillary architecture resembling that of metaplastic respiratory epithelium.^{4,10,21,24} They are predominantly solid and rarely undergo mineralization. When cysts occur, the fluid is less oily and dark than in adamantinomatous tumors. As a result of the absence of calcification and minimal cyst formation, complete curative surgical resection may be obtained more often than with adamantinomatous or mixed craniopharyngiomas.^{10,17,23} Histology does not affect the risk for recurrence after subtotal resection or the response to radiation therapy (RT).

Microscopic islets or “fingers” of adamantinomatous tumor embedded in densely gliotic parenchyma are frequently seen when the tumor arises in the region of the tuber cinereum, hypothalamus, and floor of the third ventricle.^{21,23,25-29} The gliotic reaction of Rosenthal fibers and fibrillary astrocytes, varying between several hundred microns to millimeters in thickness,²⁶ effectively separates tumor from brain, thus providing a safe plane for surgical dissection.^{12,23,28,30} The presence of this gliotic tissue on surgical pathology is associated with a decreased risk for recurrence following a gross total tumor resection.²³

37.3 Radiology

The role of neuroimaging is to establish a preoperative diagnosis and then define the location and extent of the cystic, solid, and calcified portions of the tumor and its relationship to the

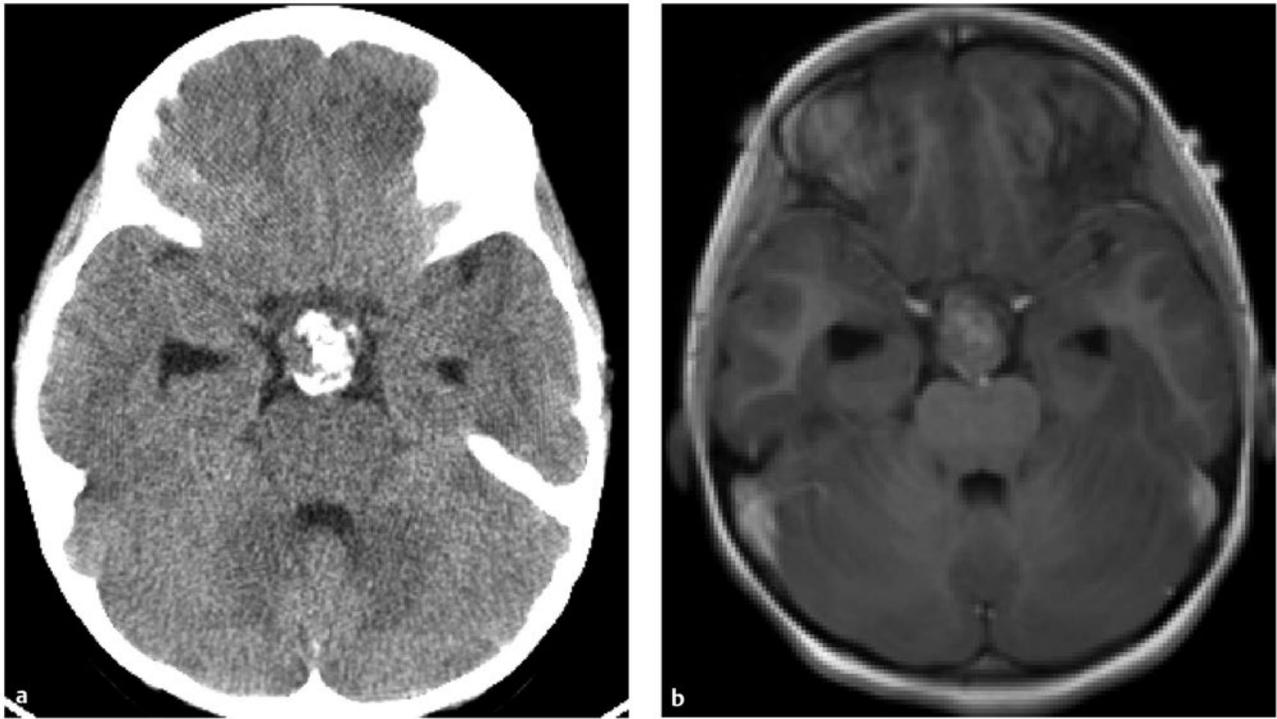

Fig. 37.1 (a) Noncontrast computed tomographic (CT) scan demonstrating calcified portion of tumor. (b) Corresponding contrast-enhanced T1 axial magnetic resonance image. Note the nonenhancing portion, representing the calcification seen on CT.

distorted normal anatomy. Radiographic evaluation includes computed tomography (CT), magnetic resonance (MR) imaging, MR angiography, and, where available, MR spectroscopy.^{31–33} Vascular anatomy can be well demonstrated by MR imaging and MR angiography, obviating the need for invasive cerebral angiography.³²

CT and MR imaging have complementary roles in the diagnosis of craniopharyngiomas^{31,32,34} (► Fig. 37.1). CT is superior in the detection of the varied and complex calcifications. Noncontrast CT usually demonstrates a suprasellar and often intrasellar mass with calcifications, as well as hypodense solid and cyst components. The low density of the cystic component is usually greater than the attenuation of cerebrospinal fluid (CSF). A small percentage of craniopharyngioma cysts may be of high density.³¹ CT shows secondary changes in the skull base, such as enlargement of the sella turcica and/or erosion of the dorsum sellae. When MR imaging is available, contrast-enhanced CT is unnecessary.

MR imaging and MR angiography provide valuable information about the relationships of the tumor to surrounding structures, delineating the involvement or displacement of the visual pathways, hypothalamus, ventricles, and vessels of the circle of Willis. Noncontrast sagittal T1-weighted images may show the normal pituitary, leading to the correct diagnosis.³⁴ Fine calcifications may not be visible, demonstrating a paradoxically increased signal on T1 imaging or, if more substantial, exhibiting characteristic signal voids. Craniopharyngioma cysts are uniformly bright on T2-weighted sequences; however, on T1-weighted sequences, the signal intensity of the fluid may range

from hypointense to hyperintense,^{31,32,35} reflecting the heterogeneous contents. The correlation between MR imaging and the biochemical composition of cyst fluid is complex, with protein, lipid, and iron concentrations having a major influence on cyst signals.^{32,36} Cyst capsule and solid tumor vividly enhance with contrast.

Noncalcified solid craniopharyngiomas may have CT and MR imaging characteristics that are indistinguishable from those of other pediatric suprasellar neoplasms, including chiasmatic hypothalamic gliomas, germinomas, and pituitary adenomas. Proton MR spectroscopy demonstrates unique spectroscopic profiles that differentiate these tumors.³³ Craniopharyngiomas show a dominant peak, consistent with lactate or lipids, and only trace amounts of other metabolites. In contrast, gliomas demonstrate choline, *N*-acetylaspartate, and creatine, with an increased ratio of choline to *N*-acetylaspartate compared with that of normal brain; pituitary adenomas show choline peaks or no metabolites at all.

The surgeon's impression of the extent of tumor resection must be confirmed by neuroimaging. Postoperative imaging with both enhanced MR imaging and CT is best done within 48 hours to avoid the artifacts of surgical trauma.³² Residual tumor should be graded according to the method of Hoffman³⁰: grade 1, no residual tumor or calcification; grade 2, tiny (<1 mm) fleck of calcification without evidence of enhancement or mass; grade 3, small "calcific chunk" without enhancement or mass effect; grade 4, small contrast-enhancing lesion without significant mass effect; and grade 5, contrast-enhancing mass.

37.4 Clinical Presentation

In children, the slow growth of craniopharyngiomas often results in a delay between the onset of symptoms and diagnosis, with a typical prodrome of 1 to 2 years.^{37,38} The main presenting signs and symptoms of craniopharyngiomas are related to pressure upon adjacent neural structures.^{6,9,23,29,37,39–45} Headache from raised intracranial pressure is the most common complaint, occurring in 60 to 75% of cases. Visual symptoms are noted in approximately half of children. Progressive visual loss is often well tolerated by children and not diagnosed until they are noted to be sitting progressively closer to the television. Evidence of hormonal insufficiency, including growth failure, delayed sexual maturation, excessive weight gain, and diabetes insipidus, is present in 20 to 50% of children at diagnosis but is rarely the reason why a child is brought to medical attention. With progressive growth into the frontal lobes and hypothalamus and/or the onset of hydrocephalus, psychomotor slowing, apathy, and short-term memory deficits may also occur, with a decline in academic performance.

Formal preoperative neuro-ophthalmologic, endocrinologic, and neuropsychological evaluations are mandatory. On preoperative testing, 70 to 80% of children will demonstrate abnormal visual acuity or fields.^{9,23,29,37,39,46} The specific ophthalmologic deficits reflect the direction of growth of the tumor and its compression of various portions of the visual apparatus: prechiasmatic extension will compress the optic nerves, with a loss of visual acuity, whereas posterior tumors will cause chiasmatic compression, with complex visual field defects. Frank papilledema is present in approximately 20% of children.³⁸

Fewer than 30% of children are endocrinologically normal at diagnosis.^{44,45,47–49} Growth hormone deficiency is the most common finding, present in up to 75% of children. Gonadotropin deficiency is observed in up to 60% of children, and thyroid or adrenal dysfunction in approximately one-third. Diabetes insipidus is relatively uncommon preoperatively, occurring in 9 to 17% of patients.

The essential preoperative endocrine testing includes an evaluation of adrenal function and thyroid function and an assessment of salt and water balance before the initiation of steroid therapy; measurement of gonadotropins and growth hormone is also routinely performed. Failure to preoperatively recognize and correct adrenocorticotropic hormone (ACTH) or thyroid hormone deficiency or appropriately manage diabetes insipidus can result in severe morbidity or death.

37.5 Treatment

Although the optimal treatment of craniopharyngiomas remains controversial, permanent tumor control or cure should be the goal for pediatric craniopharyngiomas. At the center of the debate over potentially curative therapeutic modalities are the extent of surgical excision and the role of cranial irradiation. Total resection of the tumor has been advocated by many centers, whereas others have elected to treat with minimal surgical resection followed by RT. Palliative therapies may provide temporary relief from symptoms; however, progressive solid and cystic tumor growth is inevitable. The management of craniopharyngiomas that have failed primary therapy is associated with significantly increased morbidity and mortality.

Although most physicians would agree that complete removal is desirable for a benign tumor, the tendency of craniopharyngiomas to adhere to adjacent neural tissue and the vessels of the circle of Willis makes excision technically difficult and increases the chance of morbidity and mortality.^{16,50} In order to avoid perioperative hypothalamic damage, some surgeons prefer to perform a subtotal resection or limited surgery.^{51,52} Because partial surgery alone will nearly invariably result in tumor recurrence,^{41,53,54} adjuvant postoperative irradiation is employed to maximize tumor control. Overall, survival rates among patients treated by these two treatment methods have been comparable.^{9,16,43,51,52,54–59}

It is important to point out, however, that the quality of survival after each of these approaches has not been thoroughly documented, even though such information would provide important feedback about the efficacy of these treatment modalities. Much of the follow-up research has focused on physical morbidity, often at the exclusion of the behavioral, emotional, and cognitive sequelae that can negatively impact quality of life.

37.5.1 Surgery

Most pediatric neurosurgeons in North America and Europe favor complete microsurgical resection as the treatment of choice for newly diagnosed craniopharyngiomas.^{9,12,23,37,41,54,57,60–62} The feasibility and success of radical resection depend on the availability of surgical expertise and postoperative endocrinologic support. They also depend on an understanding of the size and extent of the tumor, whether the tumor is primary or recurrent, the clinical condition of the patient, and the societal resources available to cope with potential postoperative deficits. If the socioeconomic conditions applicable to an individual patient do not provide appropriate long-term endocrinologic support and neurologic care, functional morbidity may overshadow the merits of curative resection.

Proponents of radical surgery argue that the advances in microsurgical techniques have facilitated the treatment of these lesions, and that substitutive therapy can mediate the endocrinologic sequelae secondary to hypothalamic injury. The greater immediate morbidity of this approach may be mitigated by the fact that RT carries risks for unpredictable late neurologic, vascular, and oncogenic side effects, as well as the long-term development of neuropsychological deficits in children within the domains of intelligence, attention, memory, and psychomotor processing speed; the most salient factors increasing these risks are young age at irradiation and total dosage.^{56,63–66}

Operative Technique: Craniotomy

A categorization of the pattern and extent of growth assists in evaluating treatment options and potential surgical approaches, and in predicting outcome. Several different clinical–radiologic classification systems have been proposed^{9,30,37,38,67}; all attempt to describe the degree of vertical and horizontal extension, displacement of the optic nerves and chiasm, number of anatomical regions involved by the tumor, and overall size of the tumor. Size is graded as small (2 cm), medium (2 to 4 cm), large (4 to 6 cm), and giant (>6 cm)⁹ (► Fig. 37.2). Giant tumors may extend into multiple or all compartments, extending from the medulla to the foramen of Monro.

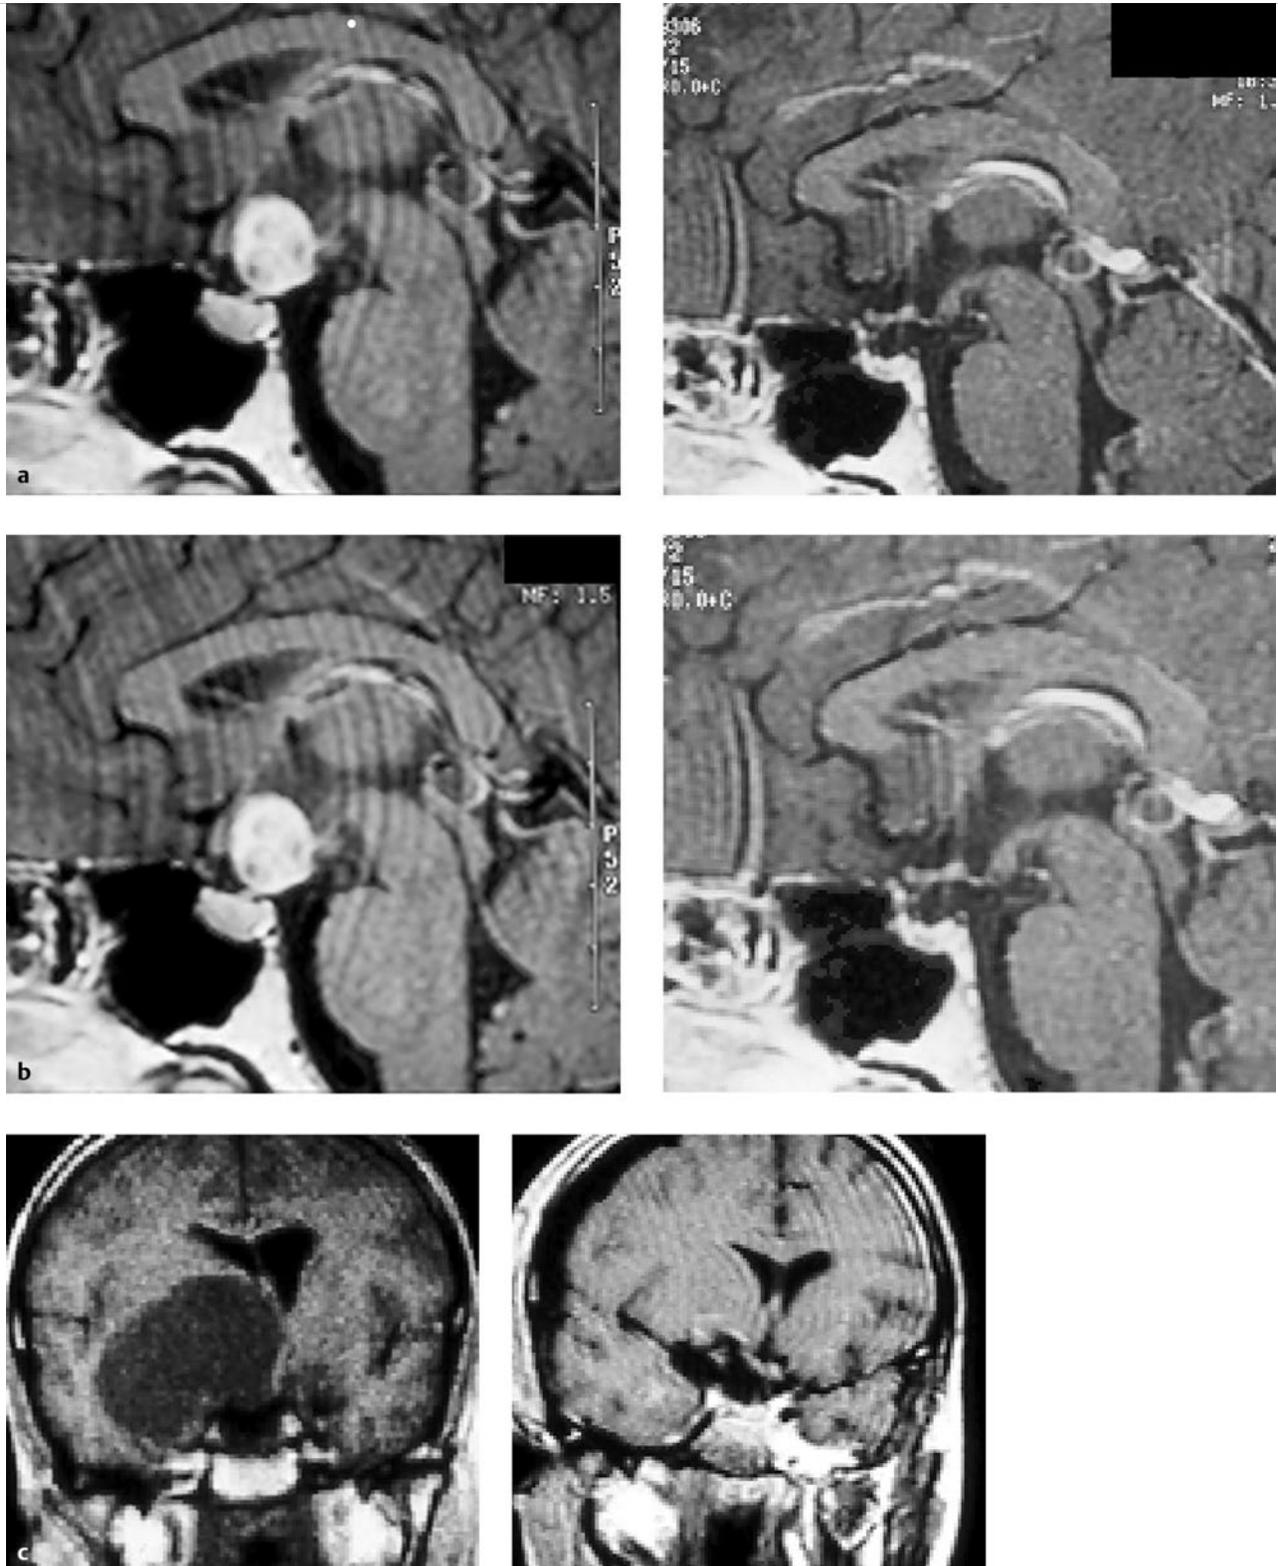

Fig. 37.2 (a) Pre- and postoperative magnetic resonance (MR) images of a small (2 cm) craniopharyngioma. (b) Pre- and postoperative MR images of a medium (4 cm) craniopharyngioma. (c) Pre- and postoperative MR images of a large (5 cm) craniopharyngioma. (continued)

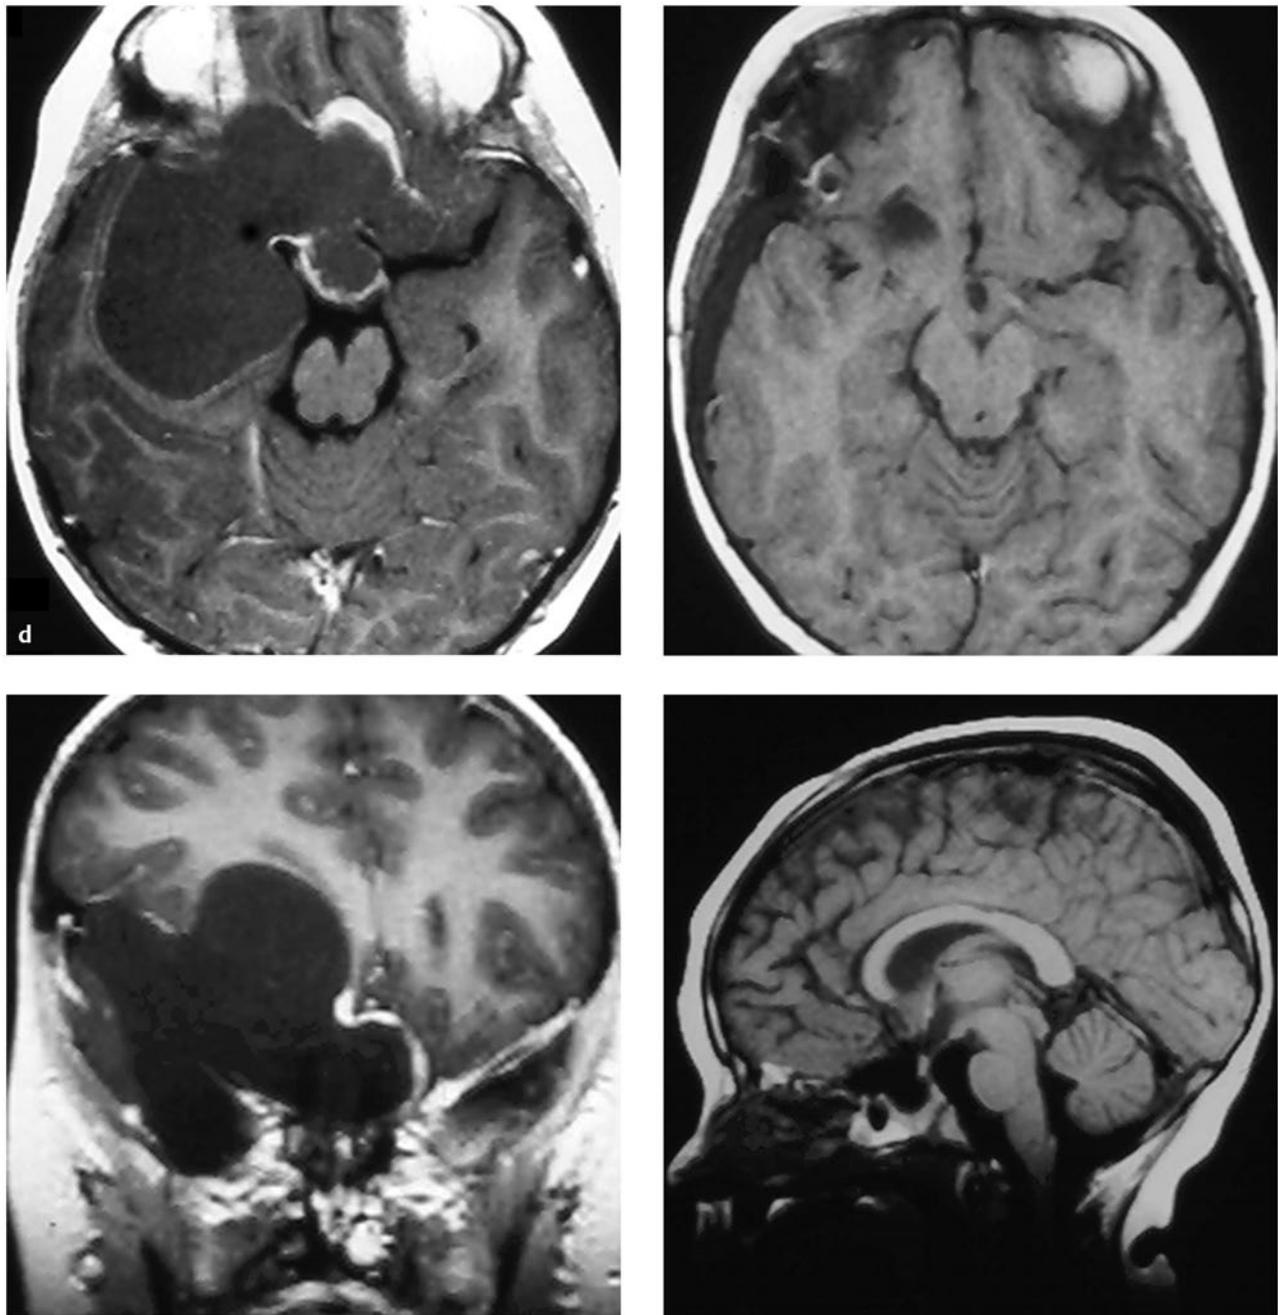

Fig. 37.2 (continued) (d) Pre- and postoperative MR images of a giant (7 cm) craniopharyngioma.

A variety of operative approaches have been described and championed by different surgeons, including the subfrontal,^{6,12,28,68} pterional,^{9,69,70} bifrontal interhemispheric,^{71,72} subtemporal,⁷³ transcallosal,¹⁷ and transsphenoidal approaches.^{70,74–77} Modified skull base techniques expanding on the pterional approach, including orbitofrontal and orbitozygomatic approaches, have gained popularity over the past two decades.^{54,62} Surgical adjuncts, including ultrasonic aspirators, frameless stereotaxy, and rigid and flexible neuroendoscopes, should be available and utilized when appropriate.

The senior author prefers a skull base modification of the pterional craniotomy,⁹ with the additional removal of the supraorbital rim, anterior orbital roof, and zygomatic process of the frontal bone. This approach offers the shortest, most direct route to the suprasellar region and minimizes or eliminates the retraction of normal brain. Tumors extending from the pontomedullary junction (► Fig. 37.2d) to above the foramen of Monro can be removed through the pterional approach. In no patient is a cortical resection⁷⁸ or sacrifice of the olfactory nerve³⁰ necessary.

Dexamethasone (0.1 mg/kg), phenytoin (15 mg/kg), and cephalexin (25 mg/kg) are administered after induction and intubation. Mannitol (0.25 g/kg) is then given at the time of skin incision to help maximize brain relaxation. The diuretic effect is maximal within the first hour of surgery, long before manipulation of the pituitary stalk and hypothalamus may produce the diabetes insipidus that complicates fluid and electrolyte management. Before the dura is opened, either intraoperative ultrasound or frameless stereotaxy is used to determine the location and extent of the tumor and its relationship to the operative exposure.

Throughout the surgery, retraction of the brain is minimized. Mannitol, hyperventilation, and gradual drainage of the CSF through the opened sylvian fissure and basal cisterns will usually provide excellent relaxation, even in the presence of moderate degrees of hydrocephalus. Ventricular drainage is reserved for cases refractory to these maneuvers or when the use of an intraventricular endoscope is anticipated (*vide infra*). Although hydrocephalus is present in 15 to 66% of patients,^{9,12,23,37,43,69,72,79} preoperative shunting is reserved for patients with severe symptoms of increased intracranial pressure that is unresponsive to medical management.

Because these tumors often extended diffusely throughout the suprasellar cisterns, displacing and distorting normal structures, identification of the vascular anatomy provides essential landmarks. Starting laterally, the sylvian fissure is widely split, and the distal branches of the middle cerebral artery are identified. The arachnoidal dissection proceeds medially to the main trunk of the middle cerebral artery, which is followed proximally to the ipsilateral carotid bifurcation, anterior cerebral artery, and internal carotid artery. As the carotid is followed proximally to the clinoid, the optic nerve, chiasm, and/or tracts are identified in relation to the tumor.

The premature decompression of a craniopharyngioma, especially a cystic tumor, causes the tumor capsule and arachnoid to become redundant, obscuring the planes of dissection. Working in the prechiasmatic, optic-carotid, and carotid-tentorial triangles, the surgeon develops and maintains an arachnoidal plane between the intact tumor and the branches of the ipsilateral carotid and vessels of the circle of Willis, preserving all of the vessels and their perforating branches. This plane is developed posteriorly until the basilar artery is identified. In primary tumors, the membrane of Lilliequist invariably separates the tumor from the basilar artery.

Once the vascular anatomy had been identified and separated from the tumor, the cyst is aspirated and the solid internal component debulked. Care is taken to preserve the capsule of the tumor. Again with the surgeon working in the parachiasmatic spaces and maintaining arachnoidal planes, the tumor is progressively dissected free from the optic nerves, the contralateral carotid and its branches, and the inferior aspect of the optic chiasm. An attempt is always made to identify and preserve the pituitary stalk; this can be accomplished in 20 to 30% of the patients. When the stalk cannot be separated free from the tumor, it is sectioned as distally as possible to prevent undue traction on the hypothalamus. After the tumor is dissected free from the entire circle of Willis, the pituitary stalk, and the optic apparatus, the capsule is grasped, and with continuous traction and blunt dissection, the gliotic plane is developed, which allows the tumor to be delivered from its attachment to the

hypothalamus in the region of the tuber cinereum. After the tumor is removed, the entire bed must be inspected for inadvertent residual disease. A micromirror or angle endoscope is used to view the undersurface of the chiasm and hypothalamus to confirm a complete resection.

If the tumor extends into the third ventricle or has a significant retrochiasmatic component, the lamina terminalis is fenestrated. The lamina terminalis is easily distinguished from the chiasm, appearing pale, avascular, and often distended by tumor. As retrochiasmatic tumor is removed, the prechiasmatic space may widen, allowing an additional avenue for dissection.

A third ventricular tumor is simultaneously delivered through the lamina terminalis as well as from below the chiasm. Placement of a 2.3-mm neuroendoscope into the lateral or third ventricle assists in monitoring the delivery of the intraventricular component of the tumor. With the endoscope, simultaneous or sequential transcallosal exposure of the intraventricular tumor¹⁷ is usually not obligatory.

When the tumor extends into the sella turcica, removal of the posterior planum sphenoidale and tuberculum sellae may be required to gain adequate intrasellar exposure.⁶⁸ After removal of tumor, any defects communicating with the sphenoid sinus must be obliterated with fat and pericranial grafts.

Operative Technique: Transsphenoidal/Transnasal Surgery

Although most craniopharyngiomas of childhood arise in the region of the tuber cinereum, a small percentage originate from more caudal craniopharyngeal duct cell rests within the sella turcica.⁷⁵ As these tumors grow, the diaphragma sellae stretches over the dorsal aspect, separating it from suprasellar structures and preventing tumor adherence to the optic apparatus, hypothalamus, and vessels of the circle of Willis. This feature of the pathologic anatomy allows a radical removal of infradiaphragmatic intrasellar tumors through a transsphenoidal/transnasal approach.^{17,70,74,75,80} From 3 to 15% of pediatric craniopharyngiomas may be amenable to transsphenoidal/transnasal resection.^{37,81}

Transsphenoidal/transnasal surgery in young children may present anatomical difficulties related to the small size of the bony structures and to the lack of a pneumatized sphenoid sinus. The presence of a conchal or pre-pneumatized sphenoid sinus is not a contraindication to transsphenoidal surgery; however, the bone must be meticulously drilled or chiseled under fluoroscopic control to obtain wide access to the sella turcica.⁷⁵ Thick bones of the sinuses and skull base may require drilling near the sella, planum, and optic nerves. Abe and Lüdecke⁸² reported that incompletely pneumatized sphenoid sinuses required drilling in 46% of patients in their series of 11 children, but this did not hinder resection in any case. We recommend using an irrigating drill with a diamond bur when the bones of the skull base are drilled to decrease the risk for thermal or mechanical injury to the optic nerves, chiasm, and internal carotid arteries. Other useful adjuncts include a micro-Doppler probe to better identify the carotid artery and stereotactic image guidance with high-resolution CT in addition to standard preoperative MR imaging.

As noted by Im and colleagues,⁸³ the poorly pneumatized sinuses and smaller facial structure of children create an even

narrower working corridor. They accomplished gross total resection of six large craniopharyngiomas via the transsphenoidal approach by relying on the cystic nature of all six tumors, the infradiaphragmatic origin of the tumors, and the use of micro-mirrors for lateral visualization. They noted that predominantly cystic tumors are more common in adults than in children, and early decompression can aid in the extirpation of such tumors and removal of the capsule from surrounding structures. With the advent of angled endoscopes and improved optics, micro-mirrors will likely become obsolete. Nevertheless, taking advantage of the cystic nature of craniopharyngiomas is a critical surgical pearl that facilitates transsphenoidal/transnasal surgery via a long, narrow corridor.

Other technical aspects of the operation do not differ significantly from those for similar surgery in adults, particularly in regard to the overall approach and tumor resection^{69,70,75,77,84} however, because of the rarity of these tumors, this approach should be utilized only by surgical teams with adequate experience.⁸⁵

After a wide dural opening, the normal, ventrally displaced pituitary gland is encountered. If the gland obstructs the visualization of the tumor, the pituitary gland should be incised in the midline, then gently pushed laterally to obtain exposure of the dorsally located craniopharyngioma. Once an initial plane of cleavage between the tumor and sellar wall is established, the capsule is opened, with drainage of cyst fluid and debulking of solid neoplasm. Following this internal decompression, the capsule is dissected from the walls of the cavernous sinuses and pituitary gland to complete mobilization of the intrasellar tumor. When the superior capsule adheres to the diaphragma, it must be incised and resected. As the superior craniopharyngioma is delivered, the remaining attachment of the tumor to the pituitary stalk is visualized and detached with bipolar coagulation and sharp dissection to achieve a gross total resection. Resection of the diaphragma invariably produces an intraoperative CSF leak. Obliteration of the sella and sphenoid sinus with a free fat graft is mandatory. Several days of postoperative lumbar drainage is recommended.⁷⁰

Outcomes of Surgery

Craniotomy

Radiographically confirmed total resection can be accomplished in 80 to 100% of primary tumors in children.^{9,12,23,37,54,60–62,72} Following radiographically confirmed total resection (Hoffman grade 1 or 2), no adjuvant therapy is administered.⁸⁶ Accessible tumor demonstrated on postoperative MR imaging or CT that was inadvertently left unresected at primary surgery should be removed. A second operation within several weeks of a primary surgery does not entail any significant added risks or technical difficulty. Recurrence rates following total resection range from 0 to 20% (► Table 37.1).^{9,12,23,37,54,57,60} Most recurrences in children develop within 2 to 3 years.^{9,12,23,37,60,87–89} Tumor recurrence may be distant from the primary site as a result of implantation at the time of initial resection,^{60,90,91} and this has been seen in 7% of recurrent tumors treated by the senior author.⁹² Reoperation can be curative, especially with solid tumors; however, scarring from previous surgery may increase the technical difficulty of surgery (vide infra).

Table 37.1 Recurrence after primary resection

	Total number of children	Radical surgery	Recurrence	Mortality
Choux et al (1991) ³⁷	454	251	19%	4%
Fahlbusch (1997) ⁶⁹	30	13	17%	0
Hoffman et al (1992) ¹²	50	45	29%	2%
Tomita and McLone (1993) ⁶⁰	27	23	5%	0
Elliott et al (2010) ⁶²	57	57	20%	3%
Yasargil (1996) ²⁰⁸	61	61	10%	2%

The rates of perioperative mortality following radical surgery have decreased substantially in the last decade, from between 6 and 11% to between 0 and 4%.^{9,12,22,23,28,37,53,54,60,62,70,79,88,93} The philosophy²⁹ and experience of the surgeon^{23,57,79} significantly affect the likelihood of achieving a curative total resection with a low incidence mortality or disabling morbidity. Centers performing fewer than two operations for radical resection per year had a good outcome in 52% of cases, compared with 87% of cases for institutions that performed radical surgery more often.⁵⁷ In addition, the size of the tumor, severity of preoperative deficits, and presence of hydrocephalus all impact on postoperative morbidity,^{17,79} although not on disease control.⁹⁴

Younger age has historically been associated with worse outcome, regardless of the therapeutic modality. De Vile et al reported age younger than or equal to 5 years as a predictor of poor outcome after primary surgery and at long-term follow-up, and of a decreased chance of cure.⁷⁹ Rajan et al also reported a linear trend of improved disease- and treatment-related survival with increasing age in children with craniopharyngioma.¹⁶ Erşahin et al noted improved outcome and less chance of recurrence in children older than 10 years of age at the time of diagnosis.⁹⁵ Several authors have reported higher rates of tumor recurrence in children younger than 5 years.^{37,79,96,97} However, some studies reported no associations between age and outcome, survival, rates of recurrence,^{98–101} or obesity and overall health status.¹⁰²

In the senior author's experience, radical resection alone at presentation and recurrence offered disease control in 89.5% of 19 patients younger than 5 years with no operative mortality and minimal morbidity.¹⁰³ One patient developed a fusiform dilatation of the internal carotid artery and experienced a small recurrence that was successfully treated with gamma knife radiosurgery. There was one late mortality in a young child who underwent subtotal resection at New York University after having failed multiple resections, aspirations, and at outside hospitals. Although disease control was not obtained in this patient, death was secondary to an endocrine crisis unrelated to tumor progression. Overall, disease control was successfully achieved in the vast majority of our pediatric patients with surgical resection alone—avoiding the significant risks of irradiation in this young population of patients. Furthermore, we found no difference between the rates of overall survival, neurologic deficits, endocrine deficiency, hypothalamic dysfunction, and quality of life in patients 5 years or younger and those in patients older than 5 years in our entire series of 86 children.

Endocrine disturbances are common after radical resection as a result of hypothalamic manipulation and pituitary stalk sectioning.^{7,9,37,60,104,105} Endocrine morbidity may be more severe when tumor resection involves bilateral manipulation of the hypothalamus.¹⁷ Although a significant percentage of deaths in earlier series were attributable to pituitary insufficiency,^{105,106} this is uncommon today, provided adequate socioeconomic resources are available.

Hormonal replacement therapy is required in approximately 80% of the children.^{23,44,47–49,107} Thyroid and cortisol replacement therapy is administered as necessary. Diabetes insipidus is universally present immediately following surgery. Over the course of the first week, diabetes insipidus may alternate with inappropriate antidiuretic hormone release (SIADH). Meticulous attention to fluid balance and electrolyte status is essential to avoid severe fluctuations from hypernatremia to hyponatremia. Permanent diabetes insipidus will develop in approximately 75% of children.^{9,23,55} Replacement with synthetic vasopressin (DDAVP) provides excellent control of diabetes insipidus in children with an intact thirst mechanism. However, the rare combination of ADH insufficiency and an impaired sense of thirst following aggressive surgery with severe hypothalamic injury remains one of the most complex management problems.¹⁰⁴

Excess weight is often the overriding concern during long-term follow-up. As Hoffman and colleagues¹² have noted, “In a society where fitness and slim bodies are praised, obesity has led to problems with peers.” Weight gain without overt hyperphagia may occur in half of all children undergoing radical surgery, although morbid obesity with lack of satiety is far less common.^{7,37,44,45,108,109} Many children may become distraught over the alteration in habitus and body image; five of our patients have required individual or family counseling to address these psychological and emotional issues. We now routinely counsel families and older children preoperatively that they may experience a 10 to 15% permanent weight gain. Bilateral hypothalamic damage, particularly in children with larger tumors, may result in an insensitivity to endogenous leptin and a disturbed feedback mechanism from the hypothalamic leptin receptors to the adipose tissue.¹⁰⁹ Preoperative weight gain and MR imaging evidence of extensive involvement of the hypothalamus may help predict the patients most at risk for severe postoperative obesity.¹⁰⁸

Although most children with craniopharyngiomas are deficient in growth hormone, some will maintain a normal or even

accelerated growth rate after surgery, often associated with hyperphagia and obesity.^{47,48} Normal or accelerated growth following surgery does not indicate the presence of normal growth hormone secretion or ensure continued growth. A complex series of metabolic events, including the activation of insulin-like growth factor-1 by hypothalamic hyperphagia and obesity-induced hyperinsulinemia, may explain this growth pattern.^{44,110} Many later fail to maintain this growth, and if growth hormone treatment is not instituted, adult height is compromised.⁴⁷ Growth hormone treatment may be recommended in these children for long-term improved growth velocity, adult height, and other growth hormone-dependent metabolic processes.¹¹¹ Even when growth hormone replacement may not affect growth, it may help decrease body mass index.¹¹²

Total removal of the tumor offers the optimal ophthalmologic recovery and outcome.³⁷ Some degree of deterioration in visual function is present in approximately 20% of children after surgery.³⁷ Maximum improvement in visual acuity and fields is noted within the first postoperative month.⁴⁶ The extent and duration of preoperative deficits, but not age, are associated with a worse outcome.^{9,23,37,93} Visual outcome from the authors' experience and current literature is summarized in ► Table 37.2

Fusiform dilatation of the carotid artery (FDCA) occurs in 10 to 20% of children several months to years following radical surgery,^{113–115} although it is underreported in the literature. In the senior author's experience of 76 consecutive children treated with aggressive microsurgical resection of craniopharyngiomas with complete follow-up imaging, almost 10% of children experienced postoperative fusiform aneurysmal dilatation of the supraclinoid carotid artery.¹¹⁵

There have been a total of 26 reported cases of FDCA following craniopharyngioma resection in children and young adults.^{114–121} The mean age at time of surgery was 10.4 years, the mean tumor size was 3.3 cm, and the mean interval from surgery to the diagnosis of FDCA was 12.5 months. FDCA lesions stabilized in 20 of 24 cases (83%) over an average follow-up duration of 6.5 years (two lesions were treated upon initial diagnosis without serial imaging^{119,121}). All 15 lesions that have been observed for at least 5 years have stabilized in size. Only two (7.7%) cases became symptomatic (headache in one patient, vision loss from optic nerve compression in another patient). No patient experienced rupture during the follow-up period.

The pathogenesis is unclear but most likely is related to operative manipulation and retraction causing injury to the vasa

Table 37.2 Visual function after radical resection

	Hoffman et al ¹² (50 children, all primary)	Yasargil et al ⁹ (68 children, 50 primary and 16 recurrent)	Tomita and McLone ⁶⁰ (27 children, all primary)	Elliott et al ⁶² (86 children, 57 primary and 29 recurrent)
Visual field				
Improved	39%	63%	62%	26%
Stable	20%	32%	19%	55%
Worse	41%	5%	19%	19%

Stable	15%	25%	30%	69%
Worse	30%	15%	11%	15%

vasorum and subsequent weakening of the muscular layer. Although RT may have contributed to the onset or progression of FDCA in three reported cases, the majority of patients (88%) had not received RT before the onset of FDCA. The natural history of FDCA appears to be dramatically different from that of radiation-induced aneurysms,^{122–126} most of which are saccular in morphology, not fusiform. Postradiation aneurysms occurred at a mean of 10 years following treatment and presented with subarachnoid hemorrhage in over 60% of cases. The putative pathogenesis of RT-induced aneurysms is endothelial damage from the ionizing radiation; smaller vessels and capillaries are usually more affected than larger-caliber vessels.¹²⁷

The pathogenesis and natural history of radiation-induced aneurysms are markedly different from those of FDCA following craniopharyngioma surgery and should not be treated in a similar manner. Our experience is consistent with that of most other authors,^{116,120,128} that FDCA may be a relatively frequent but clinically benign complication following craniopharyngioma and should be radiographically observed. If operation is required for recurrent tumor, Sutton has recommended approaching the tumor from the opposite side.¹¹⁴ For small, recurrent craniopharyngiomas with FDCA, stereotactic radiosurgery may be a useful and safe option, with high rates of reported local control.^{129–132} Direct reconstruction of the carotid artery is dangerous and should be avoided. Whether wrapping the dilatation has long-term benefit is similarly uncertain.^{113,114} Conservative follow-up with MR imaging and MR angiography is appropriate.

Transsphenoidal Resection

Total resection can be accomplished in 60 to 90% of primary infradiaphragmatic intrasellar craniopharyngiomas; however, the rate of success drops to 10 to 60% for recurrent tumors.^{69,70,76,77,81,84} In experienced hands, operative mortality ranges from 0 to 4% and

nonendocrine morbidity from 15 to 25%, with children tending to do better than adults.^{69,70,75,77,81} The incidence of new diabetes insipidus, but not of other endocrine deficiencies, appears to be less than with transcranial surgery.^{17,69,70,84} Impairment of psychosocial function is uncommon.^{69,70} Recurrence after total resection of a primary tumor develops in 0 to 43% of patients, with the incidence of recurrence substantially less in the most experienced centers.^{69,70,76,81,84}

A recent meta-analysis of the major surgical series for the treatment of pediatric craniopharyngiomas demonstrated that the patients treated with transsphenoidal/transnasal approaches had excellent outcomes.¹³³ Compared with the children who had formal craniotomies, the patients treated with transsphenoidal/transnasal surgery had better visual, neurologic, endocrinologic, and oncologic outcomes.

Directly comparing outcomes following craniotomy and transsphenoidal/transnasal surgery for pediatric craniopharyngioma may not be valid. Critical to this analysis is the identification of baseline differences between the populations of patients selected for each surgical approach (► Table 37.3). Craniopharyngiomas treated transsphenoidally tended to be smaller, more often completely or predominantly intrasellar, and often cystic in nature.^{70,134,135} These patients also had less hydrocephalus and no reported instances of elevated intracranial pressure.

Prior studies have reported worse outcomes in patients with hydrocephalus, larger tumors, and poor preoperative functional status.^{9,62,79,136} Moreover, large tumor size has been associated with increased operative mortality,⁹ neurologic and hypothalamic morbidity,^{9,79,95} a lower probability of gross total resection,^{61,79,135} and higher recurrence rates.^{79,95,137,138} The selection bias due to these baseline differences may explain the improved outcomes in the transsphenoidal surgery group in the meta-analysis. Regardless of these findings, further experience with transsphenoidal/transnasal approaches in conjunction with

Table 37.3 Comparison of baseline characteristics and outcomes following resection of pediatric craniopharyngiomas via transcranial and transsphenoidal / transnasal approaches

Variable	Transcranial series, % (No.)	Transsphenoidal Series, % (No.)	p Value
Preoperative vision deficits	53.5% (1,051 of 1,966)	68.5% (124 of 181)	<0.0001
Preoperative hydrocephalus	41.7% (678 of 1,625)	5.1% (5 of 99)	<0.0001
Preoperative elevated ICP	42.6% (729 of 1,713)	0% (0 of 138)	<0.0001
GTR	60.9% (1,693 of 2,780)	72.1% (199 of 276)	0.0003
Recurrence after GTR	17.6% (261 of 1,518)	8.0% (16 of 201)	0.0005
Operative mortality	2.6% (68 of 2,622)	1.3% (5 of 373)	0.21
Neurologic morbidity	9.4% (200 of 2,140)	3.1% (10 of 325)	<0.0001
Diabetes insipidus	69.1% (1,437 of 2,076)	23.9% (76 of 318)	<0.0001
Vision improvement	47.7% (454 of 1,051)	85.5% (106 of 124)	<0.0001
Vision deterioration	13% (263 of 2,029)	2.3% (8 of 352)	<0.0001
Obesity or hyperphagia	32.2% (439 of 1,363)	32.1% (35 of 109)	1.00
Overall survival	90.3% (2039 of 2258)	93.9% (216 of 230)	0.075

Table 37.4 Relative indications for and contraindications to transcranial and transsphenoidal resection of craniopharyngiomas

	Transcranial approaches	Transsphenoidal approaches
Indications	Large or gigantic tumors	Purely intrasellar tumors
	Cystic or solid suprasellar tumors	Intra- and suprasellar subdiaphragmatic tumors
	Tumor entirely within the third ventricle	Predominantly cystic tumors
Advantages	Excellent visualization and control of major arteries	Early decompression of tumor before manipulation of optic apparatus
		Shorter hospital stays
		Less tissue trauma and brain retraction
		Less pain
Contraindications	Intrasellar tumors	Tumors with extension lateral to the internal carotid artery
		Large or gigantic tumors
		Encasement of arteries of the circle of Willis or optic apparatus
		Suprasellar lesions with peripheral calcifications
Disadvantages	Brain retraction	Immature (conchal) sphenoid sinus
	Manipulation of optic apparatus before tumor removal	Poor control of hemorrhage (arterial injury)
		Risk for cerebrospinal fluid leak

Source: From Elliott RE, Jane JA Jr, Wisoff JH. Surgical management of craniopharyngiomas in children: meta-analysis and comparison of transcranial and transsphenoidal approaches. Neurosurgery 2011;69(3):630–643, discussion 643.¹³³

innovations in endoscopic instrumentation will undoubtedly continue to expand the indications for transsphenoidal/transnasal surgery and, ultimately, limit patient morbidity and improve overall outcomes and quality of life. ▶ Table 37.4 summarizes the relative indications, advantages, and disadvantages of the transcranial and transsphenoidal/transnasal approaches.

37.5.2 Irradiation

Despite the fact that aggressive surgery is often considered the primary treatment for craniopharyngiomas, there is a long history of employing RT in the treatment of these tumors. As early as the first half of the 20th century, RT was considered useful in the treatment of craniopharyngiomas.^{100,139} Radiation has been utilized as primary treatment following cyst aspiration, biopsy, or subtotal resection, and as salvage in the setting of recurrent disease. Kramer et al reported a series of 10 consecutive patients treated at the Royal Marsden Hospital, London, England, during the early 1950s with biopsy and cyst decompression followed by radiation.^{101,140} Doses of 55 to 70 Gy (gray) were delivered over 6 to 7 weeks with 2 million-volt roentgen rays. At 5 to 15 years of follow-up, three of the adult patients had died of unrelated causes. The remaining adults and the six children were alive without sign of recurrence, and all were considered to be “functioning well.”

Subtotal resection alone results in progression rates of 55 to 85%, as assessed in several retrospective series.^{16,59,101,141,142} Progression often occurs early in this setting, within months to a few years after subtotal resection.^{5,101} The addition of postoperative RT in the setting of gross residual disease can decrease that recurrence rate to 15 to 20% (▶ Table 37.5). Although no Phase III data exist for a direct comparison of

Table 37.5 Recurrence rates following subtotal resection alone and subtotal resection plus radiotherapy

Series	Years of study	Subtotal resection	Subtotal resection + RT
UCSF ²⁰⁹	1956–1972	5/9 (55%)	2/10 (20%)
University of Iowa ⁵⁹	1961–1986	17/20 (85%)	0/8 (0%)
CHOP ¹⁰¹	1974–2001	7/9 (78%)	3/18 (16%)
St. Jude ⁵²	1984–2001	6/7 (86%)	2/15 (13%)

Abbreviations: CHOP, Children's Hospital of Philadelphia; RT, radiotherapy; UCSF, University of California, San Francisco.

subtotal resection alone versus subtotal resection followed by RT, the abundant retrospective data, although imperfect, demonstrate improved local control with the addition of RT following the subtotal resection of tumor.

RT has also been shown to be efficacious in the setting of recurrent disease. Relatively modern series show effective salvage of patients with recurrent disease,^{52,55,101,143,144} and it appears that the use of RT at the time of recurrence or progression yields local control rates similar to those achieved when RT is used in the early (1 to 3 months) postoperative period (▶ Table 37.6). Furthermore, overall survival remains high (85 to 100%) in the salvaged groups.

Given the ability of RT to effectively salvage recurrence and maintain high overall survival rates, the argument could be made to postpone RT until the time of recurrence. However, given a median time to progression of only 12 months in patients with subtotal resection,¹⁴² there may not be much advantage gained with this approach except in young children, who may

Table 37.6 Outcome based on the time of delivery of radiotherapy

Series	Years	Early (No. of patients)	Delayed (No. of patients)
JCRT ⁵⁵	1970–1990	82% local control (37)	83% local control (6)
CHOP ¹⁰¹	1974–2001	84% local control (18)	83% local control (22)
St. Jude ⁵²	1984–2001	86% local control (15)	87% local control (8)
Christie Hospital ¹⁴³	1976–2002	79% 10-year PFS (42)	77% 10-year PFS (44)
University of Seoul ¹⁴⁴	1985–2002	91.2% 10-year PFS (25)	91.3% 10-year PFS (25)

benefit from a delay that allows further brain development. These children should be followed closely with MR imaging and treated with irradiation at the first sign of radiographic progression.

Dose and Volume

It is not clear if there is a dose–response relationship for craniopharyngiomas. Three series have noted a dose response for local control with doses higher than 54 to 60 Gy.^{56,145,146} However, the vast majority of series in the literature do not report a dose response,^{59,147} and the reported high local control rates have been achieved with doses of 54 to 55.8 Gy.^{52,55,101} Given the potential increased risks for optic neuropathy and necrosis with doses of 60 Gy or more, most radiation oncologists use 54 to 55.8 Gy (in daily fractions of 1.8 Gy) in the treatment of craniopharyngiomas.

Treatment planning for RT relies on the accurate delineation of tumor on CT and MR imaging. The volume of RT is defined as the tumor with a margin. It is important to include the full extent of the cystic components of the tumor in the treatment volume. If cysts have been drained, the target volume should be based on the decompressed volume, including the full extent of the cyst wall. Thus, the gross tumor volume usually includes any radiographically identified enhancing or nonenhancing tumor and cyst/cyst wall. This classically has been expanded by 10 mm to create a clinical target volume; however, some authors have suggested that with highly conformal techniques, tight immobilization, and real-time imaging, the clinical target volume margins might even be decreased to 5 mm,¹⁴⁸ and most radiation oncologists favor the smaller expansions. An additional 3 to 5 mm is added to the clinical target volume to create a planning target volume.

As planning target volumes have become increasingly conformal, the importance of monitoring for cyst expansion and adaptive planning needs to be emphasized. It has been reported that 35 to 60% of patients may manifest an increase in the target volume during irradiation,^{148,149} and the increase in planning target volume on average is 11%.¹⁴⁸ In the early experience with conformal RT for craniopharyngiomas at St. Jude Children's Research Hospital, however, few patients required a change in treatment planning despite the change in volume during irradiation, primarily because relatively “large” clinical target volume and planning target volume margins of 10 mm and 3 to 5 mm, respectively, were used. As margins have become “tighter,” serial imaging during therapy should be considered

to ensure that there is no re-expansion of cysts that would require altering the target volume and/or adjusting the treatment plan. Unfortunately, it is still unclear how to identify patients who are at risk for tumor expansion during RT, and the best method for imaging during RT has not yet been defined.

Techniques of External Beam Radiation

A variety of techniques have been employed in the treatment of craniopharyngiomas. In the 1950s and 1960s, treatment was delivered with cobalt 60, usually through lateral parallel opposed portals. This meant that both temporal lobes received higher doses than did the tumor. The advent of linear accelerators changed the way radiation was delivered, allowing a “third” field or “arc rotation” such that the doses to the surrounding normal brain could be decreased. The advent of CT and MR imaging has allowed improved definition of tumor volumes and normal structures at risk, and increasingly sophisticated computer software has advanced treatment planning and delivery.

Conformal Radiation Therapy and Intensity-Modulated Radiation Therapy

A typical three-dimensional conformal RT plan might employ five fields to deliver the full dose to the target volume while limiting the dose to the surrounding brain to 30 to 40% of the target volume dose (► Fig. 37.3). Published data support the idea that treating conformally to small volumes results in outcomes equivalent to those achieved with conventionally planned RT. Merchant et al showed in a Phase II trial of conformal RT that the irradiated volume for craniopharyngioma could be safely reduced without compromising tumor control.¹⁵⁰ Doses of 54 to 55.8 Gy were administered to the gross tumor volume (solid and cystic components), and a 10-mm margin was added to create a clinical target volume. The estimated 3-year progression-free survival rate was 90%.

Intensity-modulated RT is a form of three-dimensional photon irradiation that utilizes “beamlets” (i.e., beams of different radiation intensity) to deliver irradiation through multiple fields. Intensity-modulated RT plans can be highly conformal and sculpt the dose around critical structures; however, this is achieved usually at the price of increased integral doses (i.e., low doses spread out over large areas) (► Fig. 37.4).

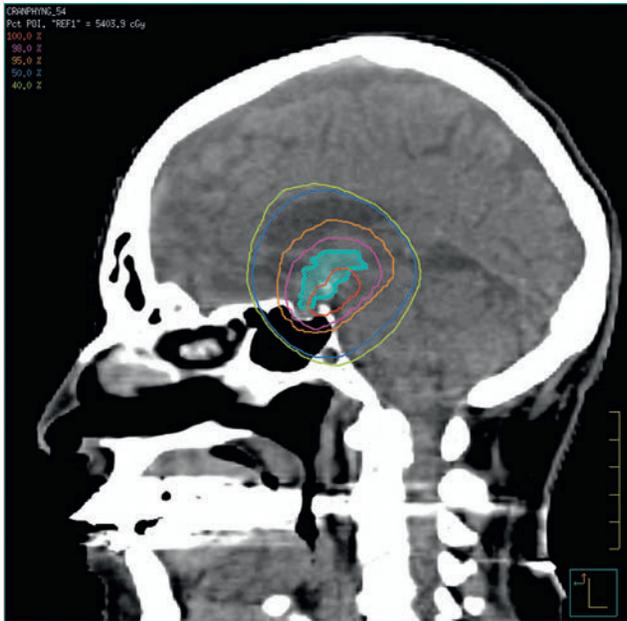

Fig. 37.3 Three-dimensional conformal radiation therapy treatment plan.

Stereotactic Radiosurgery

Stereotactic radiosurgery (the delivery of a single fraction of radiation with a nonrelocatable head frame) with either CT/MR fusion- or MR-guided planning allows submillimeter accuracy of treatment and dramatic sparing of the frontal and temporal lobes. Early publications of stereotactic radiosurgery for craniopharyngiomas reported local control rates of 78 to 100% with a median follow-up of 1 to 5 years.^{151–154} More recently, with longer follow-up, the local control rate has been reported to be on the order of 65 to 85%.^{155,156} As shown in a series from the University of Pittsburgh, complete radiosurgical coverage of the tumor and a peripheral dose of 12 to 13 Gy appear to be associated with better tumor control.¹⁵⁶ Despite its excellent ability to limit the dose to normal brain tissue, stereotactic radiosurgery has limitations in the treatment of craniopharyngioma. This technique requires the precise radiographic delineation of a target generally smaller than 3 cm; in the postoperative setting, it is frequently difficult to differentiate tumor from postoperative changes, and thus, a potential pitfall is the inadequate coverage of residual microscopic disease. Furthermore, this technique frequently is contraindicated because of tumor proximity to adjacent optic structures, which typically are limited to approximately 8 Gy.¹⁵⁷ Therefore, tumors that are not at least 5 mm away from these structures are not suitable for treatment with a single fraction and must be treated with a fractionated technique.

Fractionated Stereotactic Radiotherapy

A technique that allows fractionation and targeting of the entire area at risk, while still markedly limiting the dose to surrounding brain, is fractionated stereotactic RT. Tumors that are adjacent to or involve the optic structures can be treated in this fashion by exploiting the radiobiological advantage of fractiona-

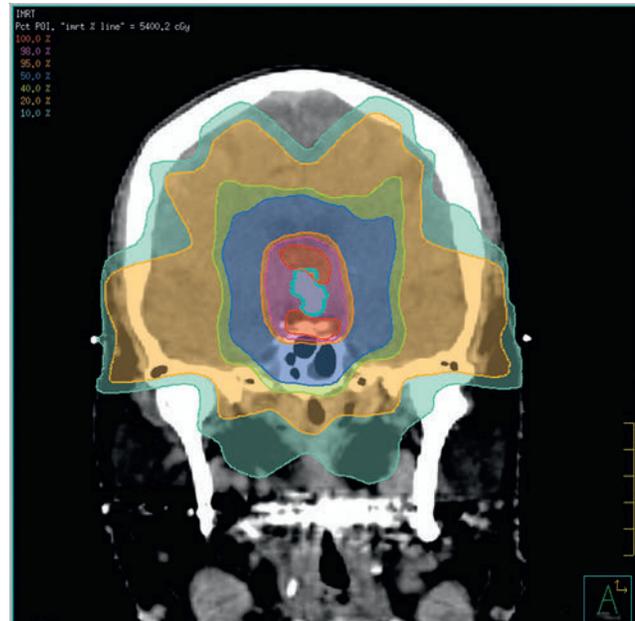

Fig. 37.4 Intensity-modulated radiation therapy treatment plan.

tion. This technique requires rigid immobilization with a relocatable head frame. Treatment is delivered on a daily basis with conventional fractionation schedules. Tarbell et al reported the feasibility of fractionated stereotactic RT in the treatment of craniopharyngioma early in the development of this technique.^{158–160} A series from the University of Heidelberg reporting on the use of fractionated stereotactic RT for craniopharyngiomas noted 100% local control at 10 years in 26 patients who were treated with a median dose of 52.2 Gy.¹⁶¹ No statistical differences have been reported in terms of tumor control with fractionated stereotactic RT between children and adult patients, and reduced toxicity has been reported with fractionated stereotactic RT.^{162–164} Overall, fractionated stereotactic RT is a suitable treatment technique for many craniopharyngiomas, and its efficacy is comparable to that of conventional RT, with control rates on the order of 90%.¹⁶⁵

Protons

Given the long survival of patients with craniopharyngiomas, efforts continue to be directed at reducing the long-term morbidity associated with radiation by further refining the delivery of RT. Protons are a means to do this, and their use in the treatment of craniopharyngiomas goes back several decades. The physical characteristics of protons make possible the delivery of targeted doses of irradiation with integral doses lower than those associated with intensity-modulated RT. The initial Harvard experience combining protons with photons in 5 children with craniopharyngiomas reported 100% tumor control at a median follow-up of 13 years; only 1 child exhibited "learning difficulties and slight retardation."¹⁶⁴ In a series from Loma Linda with 5 years of follow-up, tumor control was higher than 90%.¹⁶⁶ Among the 12 patients who survived, Nine children experienced no new toxicities, one child developed panhypopituitarism at 36 months, another experienced a cerebrovascular

accident at 34 months, and a third patient (who had received a course of photon RT before protons as part of the initial treatment) developed a posterior fossa meningioma nearly 5 years after the protons.

Late Effects of Radiation Therapy

The long-term sequelae of irradiation include endocrinopathies, optic neuropathy, radionecrosis, vascular injury including the development of moyamoya disease, and secondary tumors. Hypopituitarism is the main long-term complication of RT; fortunately, optic neuropathy, brain necrosis, and second malignancy are uncommon.

Pituitary abnormalities are among the most common morbidities after treatment. Although about 25% of patients manifest a hormonal abnormality before treatment, the vast majority ultimately develop some loss of pituitary function after treatment. From 79 to 97% of patients will be thyroid-deficient, and 58 to 93% of patients will be growth hormone-deficient regardless of what treatment is employed.^{52,56} Although the incidence of diabetes insipidus appears higher in patients treated with radical surgery (79 to 88%) than in those treated with RT and limited surgery (22 to 38%),^{55,101} the frequency of abnormal gonadotropin-releasing hormone secretion is lower in patients treated with surgery (27%) than in those who receive combined-modality treatment (53%).⁵²

Visual impairment due to optic nerve or chiasm damage from RT is on the order of 1 to 1.5% when doses of 55 Gy or lower are delivered with conventional fractionation, but the rate increases with higher doses.^{146,147} Radionecrosis, like optic damage, also depends on the total dose and fractionation schedules; fortunately, it is rarely encountered in the treatment of craniopharyngiomas. However, when doses of 60 Gy have been used, an incidence of 12.5% has been reported.¹⁶⁷ Late vascular events, particularly moyamoya syndrome, have been recognized in the irradiation of sellar and parasellar tumors. The incidence appears to be 2 to 4% in the treatment of craniopharyngiomas.^{55,146}

Although neurocognitive dysfunction may result from irradiation, focused techniques may lessen the impact of this sequela. Interestingly, studies that have compared neurocognitive function after radical surgery with that after limited surgery plus postoperative RT generally either favor the latter or show no difference.^{2,16,55,168} A series from St. Jude Children's Research Hospital that evaluated neuropsychometric data in patients who had been treated with surgery alone or with limited surgery plus RT showed a decrease in the mean full-scale IQ, verbal IQ, and performance IQ for the group as a whole, but there was no statistical difference between the two groups in any of these measurements.⁵² Furthermore, it appears that neurocognitive toxicity may be mostly related to surgical morbidity and, not surprisingly, to the dose of RT to particular volumes of the brain.¹⁵⁰ In another series from St. Jude Children's Research Hospital, 28 pediatric patients (median age, 7 years) treated between 1997 and 2003 with conformal RT for craniopharyngioma were evaluated serially with neuropsychometric testing. In addition to surgical morbidity, cognitive outcome as measured by longitudinal IQ was adversely affected by the percentage of total brain, supratentorial brain, or left temporal lobe volume receiving a dose in excess of 45 Gy.

Second malignancies are a long-term complication that occur following RT and offer a compelling argument against the indiscriminate use of RT in all cases of childhood craniopharyngioma. Their identification requires extended follow-up.^{55,166} Although the development of a lethal secondary malignancy in children with primary central nervous system tumors is relatively rare,¹⁶⁹ its occurrence following the treatment of a benign tumor is a devastating event. In general, cranial irradiation is associated with a higher risk for carcinogenesis at younger ages and should be employed judiciously in young children with benign tumors.

The modeling of photon and proton plans for the treatment of craniopharyngioma suggest that the increasing use of protons for pediatric craniopharyngioma may decrease long-term toxicity.¹⁷⁰ Retrospective target planning analyses in pediatric patients with craniopharyngiomas have shown that protons result in statistically lower doses to the cochlea, optic chiasm, hippocampus, dentate gyrus, subventricular zone, blood vessels, and brain.^{148,171} Furthermore, a threefold difference between the integral dose values for intensity-modulated RT and those for double-scatter proton therapy was identified, a finding that has implications for decreasing the risk for second malignancies in these children.

37.5.3 Intracavitary Therapy

The indications for intracavitary therapy and the choice of agents (radionuclide or bleomycin) are still in a process of evolution. Both tumor and patient characteristics should be considered before intracystic therapy is administered: the feasibility of radical resection, including the availability of surgical expertise and postoperative endocrinologic support; the suitability of partial resection and irradiation as treatment for the tumor; the size, location(s), and number of cysts; whether the tumor is primary or recurrent; and the clinical condition and age of the patient.¹⁷² Intracavitary therapy is most effective and often curative in primary monocystic tumors with relatively thin walls, although significant control of the cystic components of recurrent tumors can be achieved.¹⁷²⁻¹⁷⁹

Aspiration

Simple stereotactic aspiration of tumor cysts or placement of an Ommaya reservoir into the cyst for serial aspirations is never indicated as primary therapy in children and should be reserved for palliation when all other treatment modalities have failed.^{89,175,180} Frequent aspiration tends to stimulate cyst fluid production, leading to progressively shorter symptom-free intervals. Solid tumor growth is unimpeded and may extend into areas of decompressed cysts. Aspiration may be required to control cyst volume pending the therapeutic effect of intracavitary irradiation (vide infra).

Intracavitary Irradiation

Local treatment of cystic craniopharyngioma with intracavitary beta irradiation was first described 60 years ago by Leksell and Liden.¹⁸¹ The ideal agents are colloidal suspensions of beta-emitting radionuclides that are evenly distributed along the walls of cystic tumors, have tissue half-lives that allow an

adequate but not excessive dose, and have a rapid falloff in tissue penetrance to avoid corollary radiation injury to adjacent neural tissue. Clinical experience has established yttrium 90 and phosphorus 32 as the preferable radioactive isotopes, with an ideal dose of 200 to 250 Gy to the cyst wall.^{172,175,176,182} There has been controversy over the relative efficacy and safety of ⁹⁰Y compared with ³²P.^{172,173,175-177,182} In part, this happened because access to ⁹⁰Y was limited to Great Britain, Europe, and Japan. Contemporary reports show similar cyst response rates to both of these radionuclides, with the diminution or obliteration of cysts reported in 74 to 100% of cases.^{173,175-177,183-185} ³²P is currently the preferred agent, with its shorter tissue penetration and longer half-life offering the possibility of diminished injury to adjacent structures, especially the visual pathways and hypothalamus.¹⁷⁵⁻¹⁷⁷

Radionuclide is administered by stereotactic cannulation of the cyst, usually through a precoronal trajectory, with a fine needle. The use of an indwelling catheter connected to an Ommaya reservoir has been abandoned by most centers because the catheters have distal holes that may be located outside the cyst.^{175,177} Leakage of radionuclide has been reported in 10 to 22% of patients, although clinical sequelae have been rare.^{175-177,183-187}

Cyst regression after intracavitary irradiation occurs gradually over several months. Large, symptomatic cysts often require subsequent puncture and drainage during this period of involution. Durable control is seen in 80 to 96% of the treated cysts, with a complete response and permanent obliteration seen in 12 to 45% of the cysts.^{173,175-177} Intracystic irradiation does not control solid tumor growth, nor does it prevent the development of new cysts.

Treatment-related mortality is low, below 2%; however, morbidity varies among different series from 6 to 58%.^{172,173,175,188,189} Preoperative optic atrophy, intimate contact of the cyst wall with the optic nerves, previous or concurrent external beam irradiation, and the use of ⁹⁰Y, with its greater tissue half-value, are risk factors for visual deterioration.^{175,177,185} New endocrine deficiencies occur in approximately 10% of the patients; however, treatment-related diabetes insipidus is uncommon.^{176,177} Other neurologic complications and delayed cognitive deficits are rare.

Intracavitary Bleomycin

Bleomycin is an antineoplastic antibiotic that interferes with DNA production and has demonstrated clinical efficacy in squamous cell carcinomas.¹⁹⁰ The cell cycle kinetics and spatial distribution of S-phase proliferative cells in the squamous epithelium of craniopharyngioma cysts provide a rationale for the use of antineoplastic agents.¹⁹¹ An Ommaya catheter is placed into the cyst either stereotactically or at craniotomy. Several days after catheter placement, a contrast injection and CT are performed to verify that there is no leakage of cyst contents. A 1.5- to 10-mg dose of bleomycin is injected at 1- to 2-day intervals, depending on the cyst volume. Injections are repeated over a 10- to 21-day period for an average total dose of 60 to

80 mg.^{179,192} Although most centers have measured cyst fluid lactate dehydrogenase, no consistent pattern has emerged to guide therapy.¹⁷⁸ The major risk is leakage of bleomycin into the subarachnoid space or ventricles, with ensuing ventriculitis, meningitis, or vasospasm. To date, this has been reported only anecdotally (Sainte-Rose, personal communication, 1997). Visual deterioration and new hearing deficits have been noted in individual patients.^{178,192}

As with intracystic irradiation, involution of cysts occurs slowly over several months. Although the total number of patients treated remains small, the reported series demonstrate reduction in cyst volume in almost all patients, with up to 50% of patients showing complete disappearance of the cyst and indefinite remission.^{37,178,179,192,193} Bleomycin may also be used as a surgical adjunct to decrease the technical difficulty of subsequent surgical resection, particularly in patients with mixed solid and cystic craniopharyngiomas. Intracavitary therapy will produce a thick, tough cyst wall that is resistant to tearing and is easier to maintain intact, dissect, and remove en masse than the more common fragile, diaphanous cyst tissue. In contrast to other treatment modalities, bleomycin does not induce arachnoidal scarring or damage the gliotic plane between the tumor and normal hypothalamus that is crucial for safe resection.

Intracavitary Interferon

Interferon- α has been used as both systemic^{194,195} and intracavitary¹⁹⁶ therapy for primary craniopharyngiomas. Cavalheiro et al recently reported an international multi-institutional open-label trial of intracavitary interferon- α in 60 children.¹⁹⁶ Short-term disease control, defined as a decrease of more than 50% in tumor volume, was obtained in 78% of the patients. New endocrine deficiencies developed in 13%, and 30% had mild side effects. Interestingly, three of the responders had previously experienced tumor progression after bleomycin, but salvage was achieved with interferon. There was no information on long-term outcome or durability of disease control.

37.5.4 Treatment of Recurrent Craniopharyngiomas

Not every recurrent craniopharyngioma should be treated. The age of the patient, location of the tumor, nature of the previous therapy, and severity of the symptoms and signs should be thoroughly assessed before treatment is undertaken. Although neither prior surgery nor irradiation precludes the possibility of a curative resection in recurrent tumors, many surgeons have reported increased morbidity, mortality, and failure to obtain a total tumor removal compared with surgery in primary tumors.^{9,89,113,197,198}

Reoperation can be curative, especially with solid tumors.^{9,37} The nature and extent of treatment of the primary tumor influence the likelihood of curative resection at recurrence. Previous radical surgery may render further resection hazardous or even impossible. In primary tumors, there is always a dense gliotic

reaction separating the tumor from the normal neural tissue of the hypothalamus.^{29,89,198} This gliotic reaction, which forms a natural cleavage plane between tumor and hypothalamus, is probably destroyed by previous radical surgery. The increased incidence of visual, neurologic, and neuropsychological deficits accompanying surgery for recurrence may be partially related to direct hypothalamic and optic pathway injury due to the lack of this reactive glial barrier.¹⁹⁹

Because both tumor and cicatrix from previous surgery may extend diffusely throughout the suprasellar cisterns, displacing and distorting normal structures, identification of the normal vascular anatomy provides essential landmarks. The extended pterional approach with removal of the supraorbital rim and zygomatic process of the frontal bone and a wide sylvian dissection may provide a clean plane of dissection free from arachnoidal scarring and adhesions, particularly in patients who have had a previous subfrontal resection. The violation of arachnoidal planes during an aggressive primary resection may promote a dense mesenchymal reaction from the arterial adventitia to recurrent tumor, precluding the development of a safe plane of dissection and total removal. Calcific tumor is particularly likely to adhere to major vessels. Excessive, imprudent manipulation may result in carotid or basilar laceration and significant morbidity.^{60,73,199}

Recurrent tumor limited to the sella turcica is best removed through a transsphenoidal approach.⁸⁴ Careful consideration of the anatomical features, meticulous surgical technique, and extensive experience with transsphenoidal surgery are essential for success. Significant suprasellar tumor is a relative contraindication to this approach; however, transsphenoidal cyst drainage for palliation may occasionally be appropriate.

Since 1985, 43 patients have undergone an attempted total resection of recurrent craniopharyngioma; a gross total resection was obtained in 68%, compared with complete resection in 100% of primary tumors.⁶² Tomita and McLone⁶⁰ reported total resection in 55% of recurrent tumors versus 79% in primary operations. Most of these patients had a second recurrence that required further surgery and irradiation for tumor control. Hoffman et al¹² reoperated on 16 of 17 recurrent tumors and achieved a radical resection in only 5 patients. Of the 17 patients, 47% experienced a second recurrence. Yasargil et al⁹ reported 32 radical resections (19 children and 13 adults) for recurrent tumors among 144 cases; total resection was obtained in 56.3%.

In the senior author's series, 1 operative death, 2 late treatment-related deaths, and 2 deaths from tumor progression occurred, for a case mortality rate of 20%. One patient died of a radiation-induced glioblastoma 8 years after gross total removal of recurrent tumor and postoperative. Matson and Crigler⁶ had 5 postoperative deaths among 14 reoperations. Sweet¹⁹⁹ was supportive of reoperation following a less extensive primary procedure but cautions against aggressive surgery for recurrence if the patient has had previous radical surgery. All 5 of his patients with previous radical surgery died within 6 months of attempted reoperation for recurrence. In a

multicenter international study,³⁷ there was a 3.7% surgical mortality rate for primary surgery and a 13% operative mortality rate after secondary radical surgery.

Yasargil et al⁹ did not experience an increase in operative mortality; however, the long-term survival was 59.4% after secondary microsurgery, compared with 90% after operation for primary tumors. Both children and adults fared poorly, with 42.1% and 38.5% mortality rates, respectively. Yasargil comments that the difference in outcome could "largely be attributed to the difficulty in dissection at second or subsequent operation."

37.6 Quality of Life

The impact of radical resection versus limited surgery with irradiation on neuropsychological functioning and quality of life is controversial.^{2,12,23,43,200-204} In an evaluation of the psychosocial sequelae of craniopharyngiomas, regardless of treatment modality, it is critical to consider these children as having a chronic disease, requiring indefinite medical supervision for their hormone replacement therapy and periodic imaging to monitor for tumor recurrence. Children who have chronic illnesses demonstrate more psychological symptoms than normal children but fewer symptoms than patients who have overt psychological disorders, with internalizing disorders more common than behavioral problems.²⁰⁵ The entire family unit is stressed by the need for ongoing medical care, the coordination of multiple physician appointments, and the uncertainty surrounding each MR imaging session.

Isolated results on neuropsychological testing may not predict psychosocial or academic performance. Mild deficits in recent memory may not impair normal educational advancement if intelligence is adequate.¹² Merchant et al described the late effects arising from the treatment of 30 patients, half of whom were initially treated with surgery and the remaining half with limited surgery and irradiation at the St. Jude Children's Research Hospital.⁵² Results from multiple administrations of a variety of IQ measures at the time of initial evaluation and serially in 23 patients noted a decrease in IQ for the entire group but found no statistically significant difference between the two treatment groups. Additionally, 29 patients completed an abbreviated health status classification questionnaire, which indicated impairments for 23 (79%) of the group involving (in order of frequency) emotion, pain, sensation, mobility, and cognition; however, there was no statistically significant difference between the two treatment groups. Despite the lack of significant findings between the two different treatment groups, it is clear that both treatment modalities can yield notable deficits.

Riva et al²⁰⁶ evaluated the late effects of radical surgery alone for craniopharyngioma with neuropsychological and personality measures. The authors did not note any neurologic (with the exception of visual dysfunction), cognitive, or short-term memory deficits in this cohort. The study did describe the most frequent behavioral disorder as the inability to withstand frustration, followed by unmotivated fits of anger, emotional lability, and cognitive inflexibility. These symptoms can be best

understood as presumed effects on the frontal lobes arising from the surgical approach; the frontal lobes mediate aspects of impulsivity and cognitive flexibility to the hypothalamus, which plays an integral role in affect regulation. Some of the deficits associated with the impairment of frontal lobe function may be avoided by using the pterional approach, which inherently involves less retraction on the frontal lobes.

Twenty-nine children treated by the senior author with gross total resection for primary and recurrent craniopharyngioma were evaluated for quality of life and psychosocial function 4 to 17 years after surgery.²⁰⁷ Their overall psychosocial quality of life and their social-emotional and behavioral functioning for externalizing problems were within normal limits. Similar to children with other chronic diseases, they had a borderline significance range for internalizing problems. Recurrent tumors and additional surgery were associated with a decrease in physical functioning and quality of life, whereas a retrochiasmatic tumor location was moderately associated with a lowered psychosocial quality of life and with poorer social-emotional and behavioral functioning. Patients also tended to exhibit global improvement as postoperative time increased.

Retrochiasmatic tumors are more likely to involve the hypothalamus, third ventricle, and limbic system. Evidence of preoperative hypothalamic dysfunction and tumor size may predict those children at risk for postoperative intellectual and behavioral difficulties.⁷⁹ Children with retrochiasmatic tumors will be at greater risk for postoperative weight gain. These children may subsequently limit their activities, causing further anxiety and psychological stress.²⁰⁷

Many of the reports describing poor neuropsychological outcomes are from institutions having limited experience with radical microsurgical resection, multiple surgeons caring for a relatively small number of patients, or a dedicated philosophy of limited surgery and irradiation.^{2,43,57,79} In contrast, at centers with a large volume of radical surgeries and a dedicated neurosurgeon, a good outcome with normal psychosocial integration and age-appropriate academic performance is reported in over 70% of children.^{9,12,23,54,57,60,207}

37.7 Summary

In experienced centers with appropriate surgical expertise, experienced radiation oncologists, endocrinologic support, and socioeconomic resources, the curative treatment of craniopharyngiomas can be achieved in 70 to 90% of children, with maintenance of a good quality of life in more than 90%. Total surgical resection and partial resection with adjuvant irradiation have similar rates of long-term disease control, although with different immediate and long-term sequelae. Small intrasellar tumors are best treated by a transsphenoidal/transnasal route; the indications and long-term outcome for larger tumors approached transsphenoidally are evolving. Intracystic therapy may be appropriate for monocystic tumors without a solid component. Recurrent tumors are problematic; a multimodality approach should be considered, often with a combination of surgery, irradiation, and intracystic therapy to salvage the majority of these patients.

Pearls

- Both partial resection with radiation and radical resection carry similar rates of durable disease control in patients with newly diagnosed craniopharyngiomas when treatment is carried out in centers that have significant experience.
- Morbidity and long-term side effects tend to be acute after surgery and delayed with irradiation. Radical surgery carries a higher rate of endocrine deficiencies, particularly diabetes insipidus, whereas irradiation may cause length vasculopathy and the induction of secondary tumors.
- Radical surgery requires appropriate social and economic support for the long-term management of diabetes insipidus. It may not be an option where health care systems are limited or families are unable to manage the children's medications.
- Transnasal/transsphenoidal resection may be optimal for intrasellar and subdiaphragmatic tumors; however, there is a steep learning curve, particularly when the surgery is performed in young children without pneumatized sphenoid sinuses and large tumors.
- Regardless of treatment, craniopharyngioma is a chronic disease that requires lifelong attention from specialists in neurosurgery, endocrinology, and often psychology.

38 Pediatric Pituitary Adenomas

Erin N. Kiehna and John A. Jane Jr.

Although relatively uncommon, pituitary adenomas account for 2 to 6% of pediatric brain tumors.¹ Of all pituitary tumors, only 3.5 to 8.5% are diagnosed by the age of 20, and only 25% of those present before the age of 12 (primarily corticotropinomas).² Adenomas that secrete adrenocorticotropic hormone (ACTH) and growth hormone (GH) are the most common type of adenomas in prepubertal children. Prolactinomas predominate in the pubertal and postpubertal populations.³⁻⁷ Prolactin-secreting tumors account for 30 to 50% of pediatric cases, and ACTH-secreting tumors also account for 30 to 50% of pediatric cases. GH-secreting tumors comprise 10% in most series and are the most common type occurring in infants.^{3,6,8} Although nonfunctioning adenomas account for approximately one-third of adult adenomas, they constitute only 5% of pediatric adenomas.^{3,9,10} Thyrotroph- and gonadotroph-secreting adenomas are extremely rare and have been reported in only a few cases. Although they are often sporadic, they can occur in the context of multiple endocrine neoplasia type 1 (MEN-1), McCune-Albright syndrome, Carney complex, or familial isolated pituitary adenomas (FIPAs).¹¹

38.1 Indications for Treatment: Medical and Surgical

Presenting signs and symptoms are generally related to endocrine dysfunction rather than to ophthalmologic complaints but vary according to maturity of the patient. Prepubertal children and pubescent boys typically present with headaches, visual complaints, and growth delay. Pubescent girls present with pubertal arrest and hypogonadism with or without galactorrhea. Fortunately, pituitary apoplexy is a rare event in patients with pituitary adenomas, and surgical emergencies are therefore uncommon in the pediatric population.¹²⁻¹⁴ Neurosurgical emergencies include increased intracranial pressure and rapid visual deterioration that may require emergent drainage of the ventricles (in the case of hydrocephalus) or cyst contents in order to stabilize the patient.

The evaluation of a pituitary mass includes contrast-enhanced magnetic resonance (MR) imaging with dedicated pituitary imaging, a full biochemical evaluation of the hypothalamic-pituitary axis, and an ophthalmologic evaluation (see box "Preoperative Evaluation of a Pituitary Adenoma (p.503)"). Computed tomography (CT) may also be helpful to assess the bony architecture and degree of pneumatization of the sphenoid sinus. CT may also help in the differential diagnosis of pituitary adenoma versus a craniopharyngioma. Stress-dose corticosteroids should be considered for any patient with a large pituitary mass who is experiencing physiologic stress.

Preoperative Evaluation of a Pituitary Adenoma

- Imaging
 - Magnetic resonance imaging + gadolinium with pituitary sequences
 - Computed tomography for bony architecture
- Vision
 - Formal neuro-ophthalmologic examination
 - Visual fields
- Endocrine
 - Adrenocorticotropic hormone (ACTH)
 - Cortisol (a.m.)
 - Follicle-stimulating hormone (FSH)
 - Luteinizing hormone (LH)
 - Growth hormone (GH), insulin-like growth factor-1 (IGF-1)
 - Prolactin
 - Thyroid-stimulating hormone (TSH), free thyroxine (T₄)
 - Basic metabolic panel
 - Urine specific gravity and sodium

Source: Adapted from Kiehna EN, Payne SC, Jane JA Jr. Surgical treatment of Rathke's cleft cysts. In: Laws ER Jr, Sheehan JP, eds. *Sellar and Parasellar Tumors*. New York, NY: Thieme Medical Publishers; 2011:chap 10.

38.1.1 Prolactinomas

Prolactinomas are the most common pituitary tumor, comprising nearly 50% of pituitary tumors in children. They generally present at the time of or after puberty with primary or secondary amenorrhea in girls.¹⁵⁻¹⁷ Males more frequently have macroprolactinomas, which are associated with a higher incidence of neurologic and ophthalmologic signs.¹¹ The diagnosis is confirmed by measuring the serum prolactin, with values greater than 200 ng/mL diagnostic of a prolactinoma.

Medical therapy is the mainstay of treatment for these tumors. Prolactinomas should first be treated with dopamine agonists (e.g., bromocriptine, cabergoline), which are effective in normalizing the PRL levels and shrinking the tumor mass in the majority of children and adolescents (► Fig. 38.1).^{3,16,18} Cabergoline is often favored over bromocriptine because it has a longer half-life and can be administered on a weekly basis to normalize the serum prolactin levels and restore gonadal function. It has also proved to be more effective in patients whose tumors are poorly responsive or resistant to other agents.¹⁸⁻²⁴ If patients cannot tolerate the medications or if their tumors

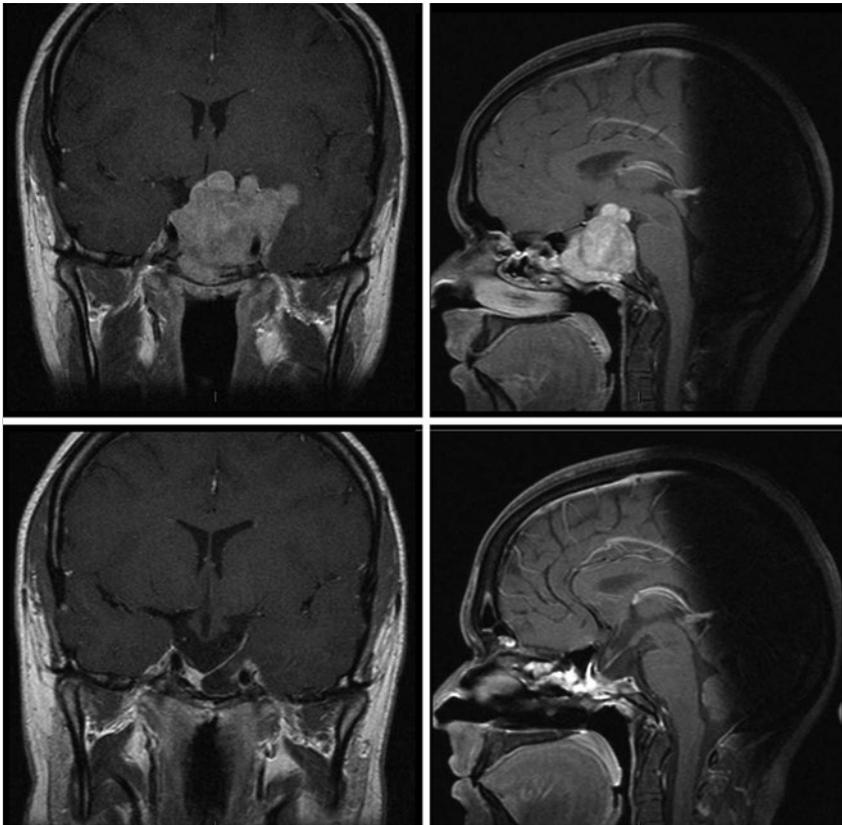

Fig. 38.1 Prolactinoma before (above) and 3 weeks after (below) medical treatment with cabergoline. Vision returned to normal within 1 week of the initiation of medical therapy.

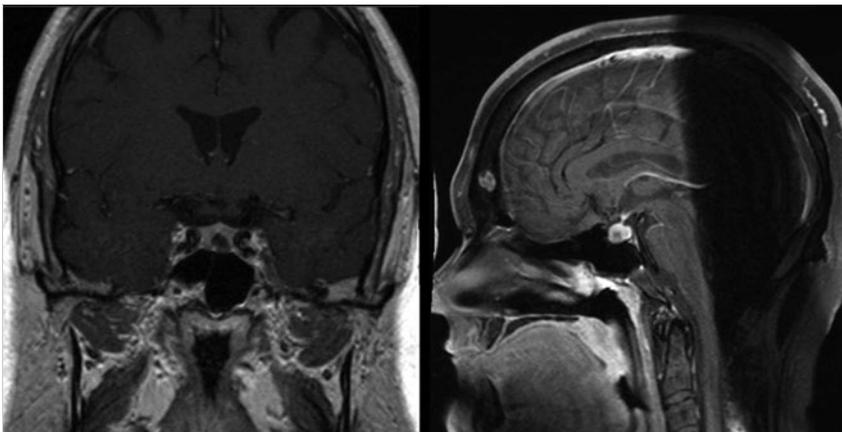

Fig. 38.2 Corticotropinoma. Coronal and sagittal T1-weighted gadolinium-enhanced images revealing a left-sided intrasellar adenoma.

are refractory to the medications, surgical remission may be obtained in 85% of patients with microprolactinomas. Lower rates of remission are expected in those with macroadenomas and those with tumors invading the cavernous sinus. However, surgical debulking may reduce the tumor burden enough to allow either radiosurgery or the recapture of effective medical therapy.

38.1.2 Corticotropinomas

Corticotropinomas (Cushing disease) typically appear in prepubescent children between 11 and 15 years of age and are a frequent cause of adrenal hyperfunction in this age group.^{25–27}

Weight gain is the common hallmark; this is accompanied by growth failure; premature puberty; facial plethora; atrophic striae in the abdomen, legs, and arms; muscular weakness; hypertension; and osteoporosis. Children may also have impaired carbohydrate tolerance (although frank diabetes mellitus is uncommon). Increases in adrenal androgens may cause acne and excessive hair growth. Corticotropinomas are diagnosed through the measurement of basal and stimulated levels of cortisol and ACTH (► Fig. 38.2).

Cushing syndrome must first be confirmed on the basis of serially elevated 24-hour urinary free cortisol (corrected for the child's body surface area) or 11 p.m. salivary cortisol measurements. Administration of low dose of dexamethasone at

midnight (15 µg/kg) does not induce suppression of morning serum cortisol concentrations in patients with Cushing syndrome. Cushing disease must then be distinguished from ectopic ACTH-producing lesions. Suppression of cortisol by more than 50% after the administration of high-dose dexamethasone at midnight (120 µg/kg) will confirm that hypercortisolism is due to an ACTH-secreting pituitary adenoma.²⁸ In many cases in which neuroimaging is not diagnostic, inferior petrosal sinus sampling can have a high specificity both for diagnosing a pituitary location with ACTH production (sensitivity of 97%) and defining laterality (in 75% of cases), but it carries a high rate of false-positive results.

Cushing disease is preferentially treated by transsphenoidal resection; this results in a surgical remission in the majority of children, with initial remission rates of 70 to 98% and long-term remission rates of 50 to 98% with multimodal therapy.^{1,3,8,25,26,29-33}

38.1.3 Somatotropinomas

Somatotropinomas (acromegaly) are rare in children (5 to 15% of pituitary tumors) but are notable for causing gigantism before growth plate fusion, diabetes, visual disturbances, and/or headaches.³ These tumors may occasionally concomitantly secrete prolactin and thyroid hormone, resulting in additional symptomatology. They may be associated with McCune-Albright syndrome or Carney complex as a result of somatotroph hyperplasia.¹¹ Somatotropinomas are usually diagnosed clinically but are confirmed by measuring circulating concentrations of insulin-like growth factor-1 (IGF-1,) which correlate with the integrated 24-hour GH secretion levels (► Fig. 38.3). Further evaluation includes an oral glucose tolerance test; failure of GH suppression or a paradoxical increase in GH production identifies patients with a GH-secreting pituitary lesion.³⁴

Acromegaly has traditionally been treated primarily with transsphenoidal surgery. In most surgical series, approximately 50 to 70% of patients with acromegaly achieve normal IGF-1 levels.³⁵⁻³⁷ Treatment with somatostatin analogues (e.g., octreotide, lanreotide) has been applied to the adult population, and the growth hormone receptor antagonist pegvisomant has been effectively

used alone or in combination with somatostatin analogues. There is little if any experience in children with these agents.

38.1.4 Thyrotropinomas

Thyrotropinomas are extremely rare but usually present as macroadenomas with mass effect symptoms, such as headache and visual disturbance, together with various symptoms and signs of hyperthyroidism.^{38,39} They are confirmed through thyroid function tests. A failure to respond to a thyroid-releasing hormone (TRH) stimulation test distinguishes a thyrotropinoma from central thyroxine (T₄) resistance. An elevated α -subunit level relative to the thyroid-stimulating hormone (TSH) level may also be useful.^{38,39}

Thyrotropinomas are primarily treated with transsphenoidal resection; however, they often require adjuvant radiation therapy. These tumors may also respond to somatostatin analogues.

38.1.5 Nonsecreting Adenomas

Nonsecreting adenomas are uncommon in childhood because they are slow-growing and often take decades before signs of pituitary insufficiency and mass effect are evident.⁴⁰ Apoplexy is a rare event in the pediatric population and is most common with nonfunctioning macroadenomas (up to 21%). Cystic formation aside from hemorrhage may occur in up to 17%.⁴⁰

38.2 Surgical Treatment

There are certain challenges to transsphenoidal surgery in children, including small nares, narrow passageways, and poor pneumatization of the sphenoid sinus. The sphenoid sinus begins to become pneumatized at about 3 years of age, and pneumatization proceeds rapidly until age 7; the sinus reaches its average normal capacity of 7.5 mL in adolescence. In approximately 5% of patients, the sphenoid bone remains minimally pneumatized (► Fig. 38.4). Because of this lack of pneumatization and the shallowness of a child's sella turcica relative to that of an adult, transsphenoidal approaches in children often

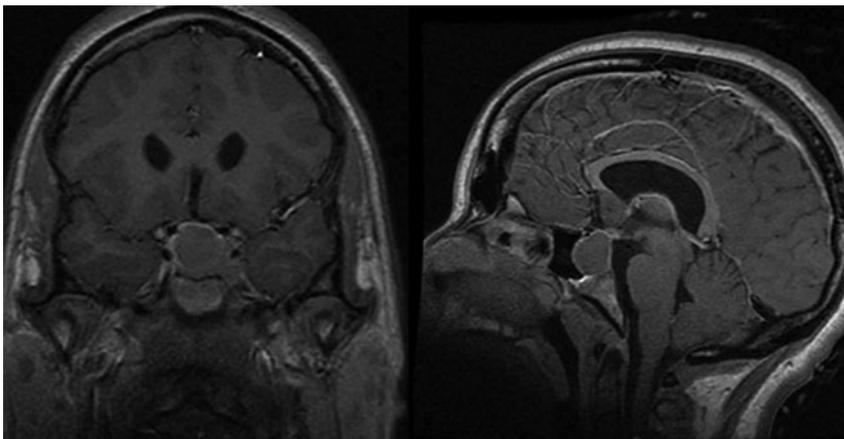

Fig. 38.3 Somatotropinoma. Coronal and sagittal T1-weighted gadolinium-enhanced images revealing a right-sided intrasellar adenoma. Note the frontal bossing and expanded diploic space on the sagittal image.

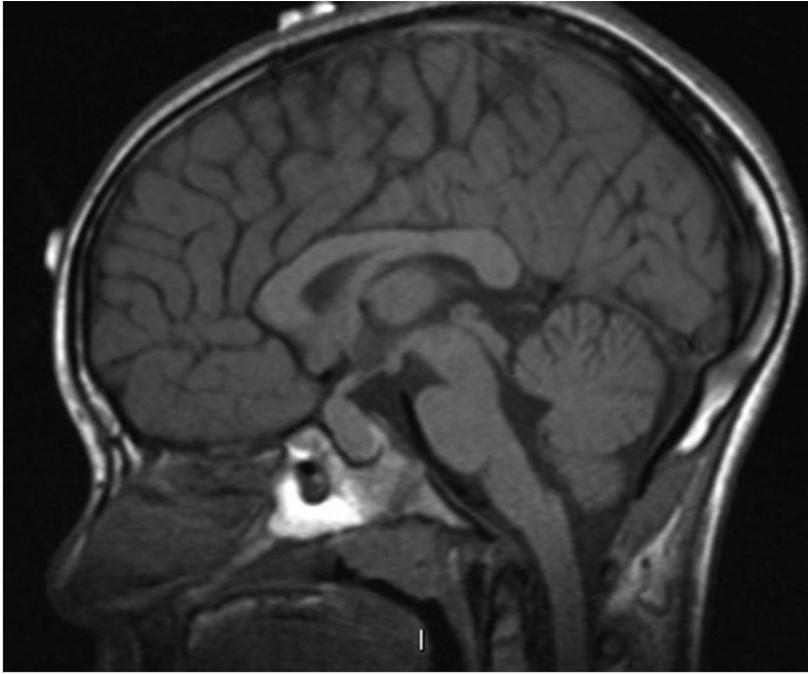

Fig. 38.4 Incomplete pneumatization of the sphenoid sinus in an 8-year-old with a pituitary mass.

require substantial drilling of the sphenoid bone, particularly in the case of microadenomas.

Regardless of the surgical technique used in the transsphenoidal approach (described below), outcomes with the two approaches are generally comparable.^{40–43} Recovery ordinarily is quite rapid following pituitary surgery, and the child often leaves the hospital within a few days and is back at school and engaging in normal activities within 2 to 4 weeks. Long-term follow-up with a specialized team, including a neurosurgeon and an endocrinologist, is crucial for optimal outcomes.

38.2.1 Microscopic Transsphenoidal Approach

Historically, pituitary adenomas were resected through a sublabial transsphenoidal approach, as described by Harvey Cushing.⁴⁴ Resection may be performed via either a sublabial or an endonasal approach. Although the benefits include a three-dimensional view, the surgeon may be limited by a fixed view and smaller field. Adequate exposure is often possible through an endonasal approach, but the sublabial approach may be favored for young children, whose small nares may not allow the unencumbered passage of transsphenoidal instruments.⁴⁵

38.2.2 Endoscopic Transsphenoidal Approach

The endoscopic transsphenoidal technique is used more commonly in adult patients; it is used less frequently in the pediatric population, perhaps because of perceived challenges, including small nostrils, narrow nasal cavities, and poor pneumatization

of the sphenoid sinus. Nevertheless, the advantages of the endoscopic approach are becoming increasingly recognized in the pediatric population.^{29,44,46} In contrast to a microsurgical technique, the endoscopic technique allows a wider field, angled viewpoints, and closer inspection.^{29,47} The approach includes a two-nostril technique, with wide exposure of the sphenoid sinus to maximize the surgeon's working space. In children, poor pneumatization of the sphenoid sinus necessitates a significant amount of drilling, and this is best performed with the use of neuronavigation.

Once the dura is exposed, the MR images should be reviewed and the micro-Doppler ultrasound probe used to assess the intercarotid distance. During the dural opening and tumor dissection, an attempt should be made to preserve the tumor and pituitary pseudocapsule. For pituitary microadenomas, every attempt should be made to preserve the tumor capsule during dissection such that it can be removed, unruptured, in one piece. For pituitary macroadenomas, the goals of surgery are to debulk the tumor and decompress the parasellar structures. When a pseudocapsule cannot be maintained, the following should be removed in a sequential fashion: first the inferior portions of the tumor, then the lateral extensions, and finally the superior portions. Early removal of the superior portions of the tumor will cause early descent of the diaphragm and increase the likelihood of incomplete tumor removal. A common location for residual tumor is at the junction of the cavernous sinus wall and the diaphragm. This location should be carefully inspected before closure.

For tumors with suprasellar extension and a prefixed chiasm, it may be warranted to remove the tuberculum and a portion of the planum sphenoidale to allow an extended transsphenoidal approach, although the increased risk for a postoperative cere-

brospinal fluid (CSF) leak must be kept in mind. When this more extended approach is to be performed and a CSF leak is anticipated preoperatively, a pedicled nasoseptal mucosal flap may be harvested at the beginning of the case to be used for the reconstruction. Otherwise, attempts are made to preserve the nasoseptal artery in the event an unexpected CSF leak is encountered and a “rescue” flap reconstruction may be necessary. The ability to switch between angled endoscopes allows the visual confirmation of complete removal of the adenoma and/or cyst contents and provides a view of the cavity. In the absence of a CSF leak, we do not repair the sellar floor so as to allow continued drainage.

38.3 Prognosis and Outcome

38.3.1 Prolactinomas

Prolactinomas are effectively treated with pharmacotherapy in as many as 89% of patients.^{12,48,49} If patients cannot tolerate the medications or if their tumors are refractory to the medications, surgical remission may be obtained in 85% of patients with microprolactinomas.

38.3.2 Corticotropinomas

The transsphenoidal resection of Cushing disease results in a surgical cure in the majority of children, with initial remission rates of 70 to 98% and long-term remission rates of 50 to 98%.^{31,32,50,51} Successful surgery results in remission of the signs and symptoms of hypercortisolism by normalization of laboratory values. Surgery is usually followed by adrenal insufficiency, and patients may require hydrocortisone replacement for 6 to 12 months. After normalization of the cortisol levels, resumption of normal growth or even catch-up growth can be observed. Generally, the patient's final height is compromised compared with his or her target height.³⁵ Some children, however, do achieve a normal final stature.

In the approximately 10% of patients with relapse or recurrence, the choice of treatment is controversial. Although repeated surgical resection can induce panhypopituitarism or permanent diabetes insipidus, hypothalamic–pituitary dysfunction is an early and frequent complication of radiation therapy.^{52,53} Conformal radiation therapy has a 2-year remission rate of approximately 70 to 80%.³⁵ Stereotactic radiosurgery with the gamma knife may further minimize the toxic effects of radiation on the brain, while still controlling tumor growth and ACTH secretion. Bilateral adrenalectomy may be the last therapeutic option in case of failure of both surgery and radiotherapy.

38.3.3 Somatotropinomas

Transsphenoidal resection for somatotropinomas is as effective in children as it is adults⁶ however, only approximately 60% of patients with acromegaly achieve normal GH levels.^{36,54} Patients with larger, more invasive tumors may benefit from adjuvant medical and radiation therapy to achieve long-term disease control.

Pearls

- Pediatric pituitary adenomas are rare entities that generally present with headaches, endocrine dysfunction, and/or visual disturbances.
- The evaluation of a pituitary mass includes contrast-enhanced MR imaging with dedicated pituitary imaging, a full evaluation of the hypothalamic–pituitary axis, and an ophthalmologic evaluation.
- Prolactinomas are the most common pediatric pituitary tumor, are usually diagnosed at the time of or following puberty, and are primarily treated with medical management.
- Corticotropinomas (Cushing disease) are primarily found in prepubescent children and are treated with transsphenoidal resection of the microadenoma.
- Somatotropinomas (acromegaly) are associated with gigantism and are primarily treated with surgery, although there may be a role for medical management.
- The early identification of pituitary adenomas and their management by a multidisciplinary team of endocrinologists and neurosurgeons are essential for disease control and normal growth and development of the child.
- Pituitary microadenomas are best removed in one piece with a pseudocapsular technique when possible.
- Pituitary macroadenomas may have to be removed in a sequential, piecemeal-type fashion, but every attempt should be made to resect the pseudocapsule.

39 Pineal Region Tumors

Tadanori Tomita

39.1 Pineal Gland

The normal pineal gland measures only 5 to 10 mm. It is histologically composed of pinealocytes (95%) and glial cells (5%). Pinealocytes are a specialized form of neuronal cells and function as neuroendocrine transducers. In lower mammals, these cells exhibit structural characteristics of photoreceptor cells. In primitive animals such as fish and amphibians, the pineal gland is a neurosensory photoreceptor organ. In mammals, it has a neurotransmitter secretory function. The function of the pineal gland in humans is not well understood, however. The pineal gland is innervated by sympathetic nerve fibers that originate from the superior cervical ganglia. The pinealocytes play a role in translating the noradrenaline input released from sympathetic nerves into a hormonal input. The pineal secretory function, specifically melatonin and serotonin synthesis and release from the pinealocytes, has been studied extensively. Serotonin concentration in the pineal gland is highest in the brain. Melatonin release in animals follows a circadian rhythm, with high serum levels during the night and low levels during the daytime. Melatonin also has an inhibitory effect on the hypothalamic-pituitary axis and at the gonadal level.¹ However, in humans, although melatonin levels are highest between the ages of 1 and 5 years and then decrease until the end of puberty,² the function of melatonin remains unexplained.³

39.2 Pineal Region

The pineal region comprises multiple structures in and around the pineal gland of the posterior third ventricle. The pineal gland is bordered by the cerebrospinal fluid (CSF) space, the third ventricle anteriorly, and the quadrigeminal cistern posteriorly. The neural structures that surround the pineal gland are the quadrigeminal plate of the midbrain inferiorly, the cerebellar vermis posteriorly, and the splenium of the corpus callosum superiorly. Lateral to the pineal gland are the posterior thalami, and anteroinferiorly is the tegmentum of the midbrain, which is continuous anteriorly with the hypothalamus. The lateral wall of the third ventricle is traversed by a hypothalamic sulcus from the foramen of Monro to the aqueduct of Sylvius. This sulcus separates the thalamus above from the hypothalamus below. The roof of the third ventricle consists of the tela choroidea and fornix.

39.3 Pathology and Pathobiology

Heterogeneous types of tumors occur in the pineal region. Tumors of pineal and extrapineal origin differ in histologic type. Those of pineal origin are germ cell tumors and pineal parenchymal cell tumors. Extrapineal tumors arise from the surrounding neural or mesenchymal structures and include astrocytomas, meningiomas, ependymomas, and choroid plexus papillomas. Another tumor in this location with papillary features, papillary tumor of the pineal region, is considered to be derived from the subcommissural organ.^{4,5}

39.3.1 Germ Cell Tumors

Tumors of germ cell origin are classified as germinomas, embryonal carcinomas, endodermal sinus tumors (yolk sac carcinomas), choriocarcinomas, and teratomas. Germinomas, which are the most common of the germ cell tumors, are composed of cells with suppressed differentiation potential. On the other hand, embryonal carcinomas are considered to be composed of pluripotential cells. They further give rise either to embryonal tumors, which consist of all three germ layers (i.e., mature teratomas and immature teratomas) or to extraembryonal tumors. The latter include choriocarcinomas through trophoblastic differentiation and yolk sac tumors through yolk sac formation. Of all the germ cell tumors, only the mature teratoma is considered to be benign. Other, nongerminomatous tumors are malignant and are included in a category of nongerminomatous germ cell tumors (NGGCTs). Elements of various germ cell tumors may coexist in a single tumor; this type of tumor is called a mixed germ cell tumor. Teratomas, on the other hand, are derived from all three germ layers of embryonal structures and are composed of well-differentiated tissues with an organoid pattern. Those composed of mature cells are benign teratomas. Immature teratomas, however, contain primitive elements derived from all or any of the three germ layers and behave in a malignant fashion.

The origin of germ cell tumors is controversial. Germ cell tumors derive from pluripotential germ cells and span a wide range of differentiation and malignant characteristics.⁶ The primordial germ cells appear in the yolk sac wall in the third gestational week. They migrate from the fetal yolk sac via the dorsal mesentery of the hindgut into the genital ridge in the sixth gestational week. They also migrate and disseminate widely throughout various tissues and organs in the early embryo. In the extragonadal location, these germ cells often remain in two midline sites: the mediastinum and around the third ventricle. This theory explains why extragonadal germ cell tumors frequently develop in the thymus and in the pineal and hypothalamic regions. However, in normal human anatomy, the primordial germ cells are not found in these locations. Sano theorized that misplaced embryonic tissues incorrectly enfolded at the time of neural tube formation become the source of intracranial germ cell tumors.⁷ Despite their early migration, these germ cells tend to develop neoplastic transformation at a much later stage of life, around puberty. One assumes that gonadotropins or gonadotropin-releasing hormones secreted by the hypothalamus at puberty may have a carcinogenic effect.⁸

Intracranial germ cell tumors show genomic alterations indistinguishable from those of their extracranial counterparts; these include gain of 12p and the X chromosome.⁹ Also, mutation of the *c-KIT* gene is common among germinomas.¹⁰

39.3.2 Pineal Parenchymal Tumors

Pineal parenchymal tumors are derived from pineal parenchymal cells within the pineal gland. These tumors possess the potential to differentiate into several cell lines, such as neuronal,

astrocytic, ependymal, retinoblastomatous, and mesenchymal components. Pineal parenchymal tumors are classified into pineoblastoma, pineocytoma, and intermediate types, depending on the cellular differentiations.¹¹ Pineoblastomas are poorly differentiated malignant tumors and belong to the group of primitive neuroectodermal tumors (PNETs). Pineocytomas, on the other hand, are differentiated and clinically benign. Some parenchymal tumors may have mixed components of pineoblastoma and pineocytoma. On immunohistochemical studies, Yamane et al reported variable immunopositivity among pineal parenchymal tumors when they used monoclonal antibodies against human pineal tissue, whereas glial differentiation seemed very rare.¹² Ultrastructural studies found that neoplastic pineal cells appeared to differentiate either toward a neurosensory pathway characterized by the presence of sensory cell elements, such as vesicle-crowned rodlets and fibrous filaments, or toward a neuroendocrine pathway.^{13,14} Cytogenetic studies showed monosomy of chromosomes 20 and 22 and gain of 1q, 5p, 5q, 6p, and 14q.¹⁵ The gene patterns of the three pineal parenchymal tumors fell in the same cluster. The pineocytomas showed high expression of *TPH*, *HIOMT*, and genes related to phototransduction in the retina (*OPN4*, *RGS16*, and *CRB3*), whereas the pineoblastomas showed high expression of *UBEC2*, *SOX4*, *TERT*, *TEP1*, *PRAME*, *CD24*, *POU4F2*, and *HOXD13*.¹⁵ Papillary tumors of the pineal region showed high expression of *SPEDF*, *KRT18*, and genes encoding proteins reported to be found in the subcommissural organ, namely *ZFH4*, *RFX3*, *TTR*, and *CGRP*.¹⁵

39.3.3 Tumors of Glial and Miscellaneous Cell Origin

Astrocytes are normally present in the pineal gland, but pure pineal gland glial tumors are exceedingly rare. Nearly all glial tumors arise from the glial tissue elements intimately surrounding the pineal gland. Astrocytomas often originate in the thalamus or the midbrain and extend to the pineal region. Glioblastomas, astroblastomas, ependymomas, oligodendrogliomas, choroid plexus papillomas, and medulloepitheliomas may occur in this region. Among tumors of mesenchymal origin, meningiomas, hemangiomas, and cavernomas may occur in the pineal region.

39.3.4 Nonneoplastic Cysts

Pineal cysts, which result from focal degeneration of the pineal gland, contain gelatinous material. The cyst wall is composed of three layers: an outer fibrous layer, a middle layer of pineal parenchymal cells with variable calcification, and an inner layer of hypocellular glial tissue.^{16,17} Other developmental cysts include epidermoid and dermoid cysts. Arachnoid cysts consist of CSF and a cyst wall composed of arachnoid membrane. These cystic lesions may have a similar appearance on neuroimages.

39.4 Epidemiology

Pineal region tumors comprise 3 to 8% of all intracranial tumors among children.¹⁸ Pineal region tumors affect more Japanese and other persons of Asian origin.^{19,20}

Intracranial germ cell tumors account for 0.4 to 3.4% of intracranial neoplasms in the United States and Europe.⁸ Germinomas are the most common variety among them, comprising 35 to 41%^{1,21} or 61 to 65%^{8,22,23} of germ cell tumors. Their average incidence in the United States is considered to be 0.1 per 100,000 persons per year.²⁴ Germ cell tumors of the pineal region tend to affect males, with a male-to-female ratio of 4:1.^{8,21} Most germinomas occur in the first three decades, with a peak in the middle of the second decade, corresponding to the onset of puberty. About 65% occur between the ages of 10 and 21 years, and only 11% occur before the age of 9 years.

NGGCTs are highly malignant. Most cases of NGGCTs occur in males in the first two decades of life. Choriocarcinomas tend to occur at a younger age (mean age, 8 years) than do embryonal carcinomas and endodermal sinus tumors (mean age, 14 and 17 years, respectively). Of choriocarcinomas, 35% occur before the age of 9 years, whereas only 10 to 12% of embryonal carcinomas and endodermal sinus tumors occur before the age of 9 years.

Teratomas in the pineal region often affect males. Most teratomas occur in children younger than 9 years, but 20% occur in persons between the ages of 16 and 18 years.

The occurrence of mixed germ cell tumors has increased because of a recent trend of aggressive tumor biopsy and the availability of tumor marker studies. In a study by Matsutani et al, 49 (32%) of 153 intracranial germ cell tumors were of mixed type.²¹ The common components frequently present in mixed germ cell tumors are germinoma and teratoma, whereas a combination of germinoma and choriocarcinoma is very rare. The correct identification of mixed germ cell tumors and NGGCTs requires adequate tumor sampling and proper preparation of the tissue for immunohistochemical and electron microscopic examination.²³

Pineoblastomas often occur in infancy and childhood,²⁵ whereas pineocytomas occur in older children and young adults.^{11,14,26,27}

The ratio of germ cell tumors to pineal parenchymal tumors was reported to be 3.6:1, whereas germ cell tumors accounted for 31% of the tumors in 282 patients of all age groups with pineal region tumors.^{28,29} In Japan, germ cell tumors are much more common than pineoblastomas, which comprise only 5.1% of pineal region tumors.³⁰

39.5 Symptomatology

The common signs and symptoms of pineal region tumors are primarily related to increased intracranial pressure due to hydrocephalus, which is present in almost all cases. Hydrocephalus is the result of obstruction of the aqueduct of Sylvius. The most common symptom is headache. The headaches usually occur intermittently initially but become more frequent and intense. They are worse in the morning and often awaken the patient during sleep. Nausea and emesis are common signs in association with headaches. Double vision may be due to either abducens nerve palsy or tectal compression. Occasional blurred vision can be due to the tectal compression but can also be related to visual obscuration secondary to papilledema. In the later stages of hydrocephalus, patients exhibit an ataxic gait and altered mental status. Papilledema is a frequent sign of hydrocephalus secondary to pineal region tumors.

Other signs are related to direct compression of the neural tissue, particularly the quadrigeminal plate and pretectal region of the midbrain. Parinaud syndrome is well-known to be pathognomonic for pineal region tumors and is present in about 50 to 75% of patients with pineal region tumors. It is due to compression or structural damage on the posterior commissure. The sudden occurrence of the setting sun phenomenon and Parinaud syndrome together with decreased mental status may be related to hemorrhage into the pineal tumor (pineal apoplexy).

Synchronous germinomas in the pineal and suprasellar regions may present with diabetes insipidus and other hormonal dysfunctions and with visual impairment.³¹ Pineoblastomas and less often germinomas may have disseminated through the CSF pathway at the time of diagnosis, which may cause various signs such as spinal cord compression and optic nerve compression.³² Precocious puberty is rare^{21,33-35} and usually occur in boys with choriocarcinoma because β -human chorionic gonadotropin (β -HCG) secondarily stimulates androgen secretion by the Leydig cells of the testes.

39.6 Diagnostic Studies

39.6.1 Neuroimaging

Computed Tomography

Computed tomography (CT) and magnetic resonance (MR) imaging are helpful for tumor detection. Associated abnormalities, such as hemorrhage and calcifications, may be better appreciated with CT. Calcifications often occur in the pineal gland.

According to Zimmerman and Bilaniuk, the youngest subject with a normally calcified pineal gland was 6 1/2 years of age.³⁶ The rates of pineal calcifications detected on CT scans were 8 to 10% from the ages of 8 to 14 years, 30% at the age of 15 years, and 40% at the age of 17 years. The presence of calcifications in children younger than 6 years, however, is abnormal and needs to be investigated for a neoplastic process.³²

On CT scans, germinomas appear as soft tissue masses that are hyperdense relative to the surrounding brain tissue. Pineal calcifications of germinomas tend to be located centrally or displaced peripherally in the tumor mass, whereas calcifications of pineoblastomas, if present, are dispersed within the tumor (► Fig. 39.1). Teratomas tend to present as inhomogeneous hypodense multiple cystic lesions with variable contrast enhancement (► Fig. 39.2). After the infusion of intravenous contrast agent, germinomas tend to enhance homogeneously. NGGCTs tend to have similar homogeneous soft tissue density, and their calcification is also similar to that of germinomas. Choriocarcinomas may have hemorrhagic foci (► Fig. 39.3). On the other hand, the appearance of teratomas is more distinct and often heterogeneous, with a variable degree of soft tissues, calcifications, and cyst formation. Pineoblastomas are relatively homogeneous and hyperdense on precontrast CT scans. After the infusion of contrast material, enhancement ranges from dense to little or none. Calcifications can occur either centrally or peripherally, but calcification is rare in pineoblastomas. There are no characteristic CT features to differentiate among pineal germ cell tumors other than teratomas and pineal parenchymal tumors.

Benign astrocytomas are often hypodense relative to the surrounding brain tissues on precontrast CT scans. They primarily

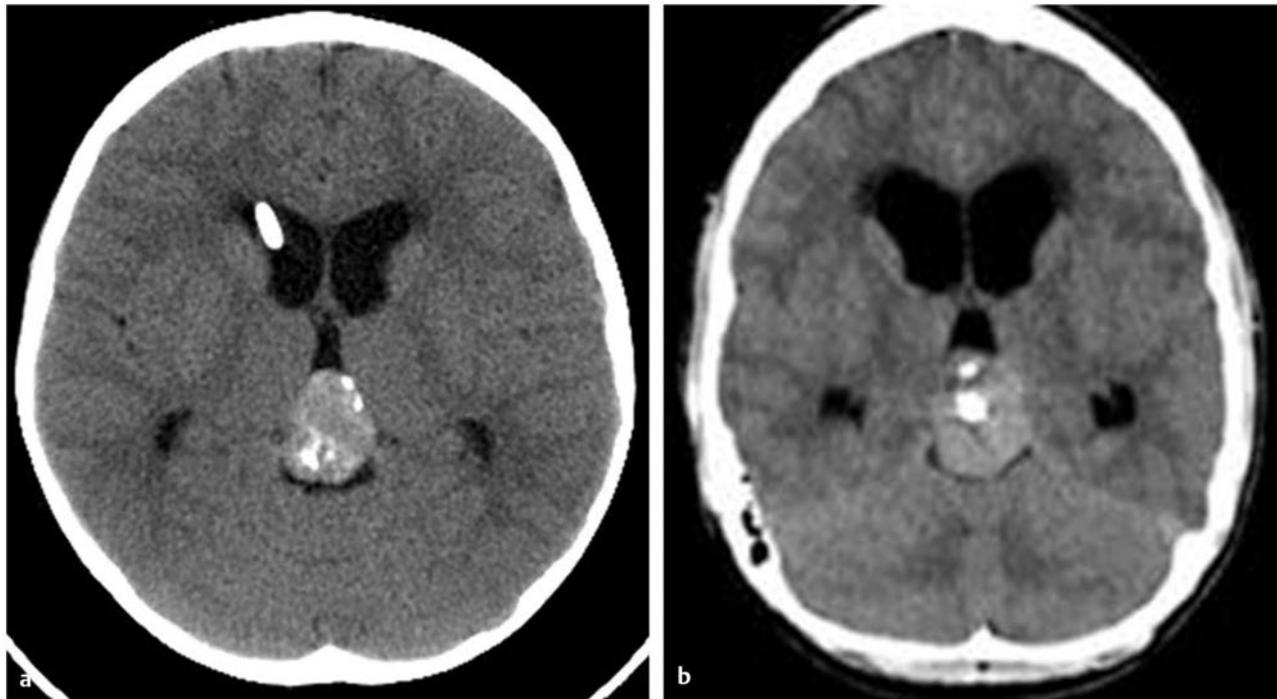

Fig. 39.1 Pineal calcification on precontrast computed tomographic scans. (a) Calcifications may be located centrally or peripherally in germinoma. (b) Calcifications may be dispersed in pineoblastoma.

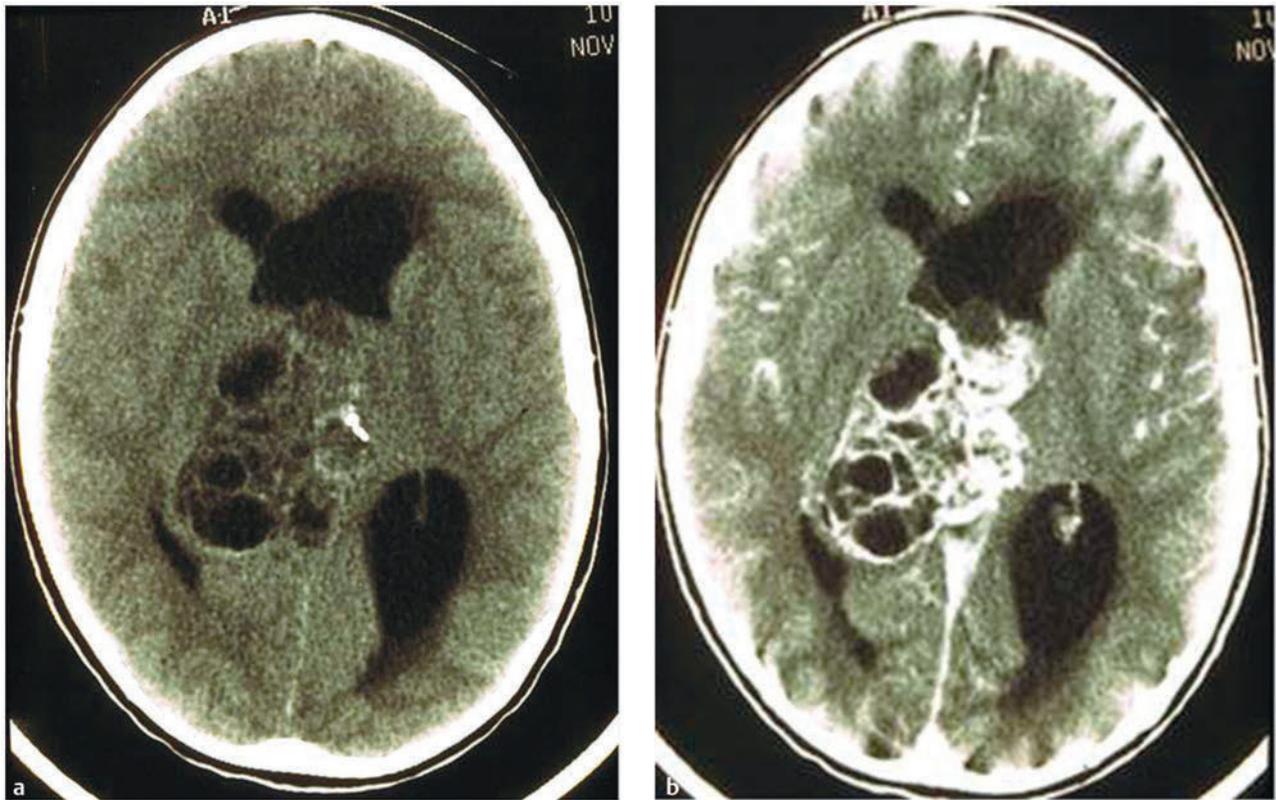

Fig. 39.2 Pineal calcification on precontrast computed tomographic scans. (a) Calcifications may be located centrally or peripherally in germinoma. (b) Calcifications may be dispersed in pineoblastoma.

originate from the midbrain or the posterior thalamus. They may be cystic, but calcification is uncommon. Contrast enhancement is variable and often inhomogeneous. Dermoid and epidermoid tumors tend to be hypodense and enhance minimally after the infusion of contrast material. They may have density equal to that of CSF, and their appearance may mimic that of an arachnoid cyst or pineal cyst.

Magnetic Resonance Imaging

Teratomas are often heterogeneous, with the presence of cyst formation and fat (► Fig. 39.4). Germinomas show low signal intensity to isointensity on T1-weighted images. They show high signal intensity or are isointense on T2-weighted images.³⁷ After the infusion of contrast material, germinomas show enhancement. Malignant NGGCTs may show variable signal intensity that is partly due to the presence of hemorrhage.³⁸ Pineoblastomas are hypo- or isointense on T1-weighted images, and variable degrees of enhancement are noted with poorly defined margins.³⁹ In general, the MR imaging signal characteristics are usually nonspecific,^{36,38} and correlation with the patient's age, sex, and other associated factors needs to be analyzed for diagnostic purposes.³⁹ Concurrent masses in both the anterior and posterior parts of the third ventricle strongly suggest germ cell tumor, germinoma in particular (► Fig. 39.5). Rates of occurrence of multiple germinoma lesions in the third ventricle may vary: 6.0 to 8.5%,^{8,21} 15%,⁴⁰ or 32 to 57% of cases.^{37,40,41} The frequency of

this multiplicity has increased with the use of more sensitive neurodiagnostic methods. For instance, Sugiyama et al reported that the frequency of synchronous lesions in pineal and suprasellar germinomas increased from 4.2% before to 17.4% after the introduction of MR imaging.³¹ In my personal experience with 43 patients who had pineal germ cell tumors treated from 1988 to 2010, 12 (28%) showed synchronous anterior and posterior third ventricle lesions. Of these 12 patients, 10 presented with diabetes insipidus. When a patient with a pineal region tumor presents with diabetes insipidus, the pituitary stalk and the tuber cinereum should be carefully investigated in order to detect multiplicity of the lesions.

Among patients with either unilateral or bilateral retinoblastomas, 3% have pineal parenchymal tumors (trilateral retinoblastoma). A history of retinal disease or evaluation with neuroimaging of the orbits enables the differentiation of pineoblastomas from other tumors in such a case.

Pineal region tumors are frequently associated with hydrocephalus. Pineal cysts, which are present in 2.4% of the normal population, are rarely symptomatic and usually remain stable in size.¹⁶ They have a contrast-enhancing cyst wall and subtle hyperintensity of the cyst contents. Mostly, they are single cysts, although occasionally a multicystic appearance is noted. Large cysts occasionally show radiographic evidence of tectal compression despite the absence of hydrocephalus. The occurrence of hydrocephalus is very rare. Fain et al reported that of 20 patients with symptomatic pineal cyst, 8 were noted to be hydrocephalic.¹⁷

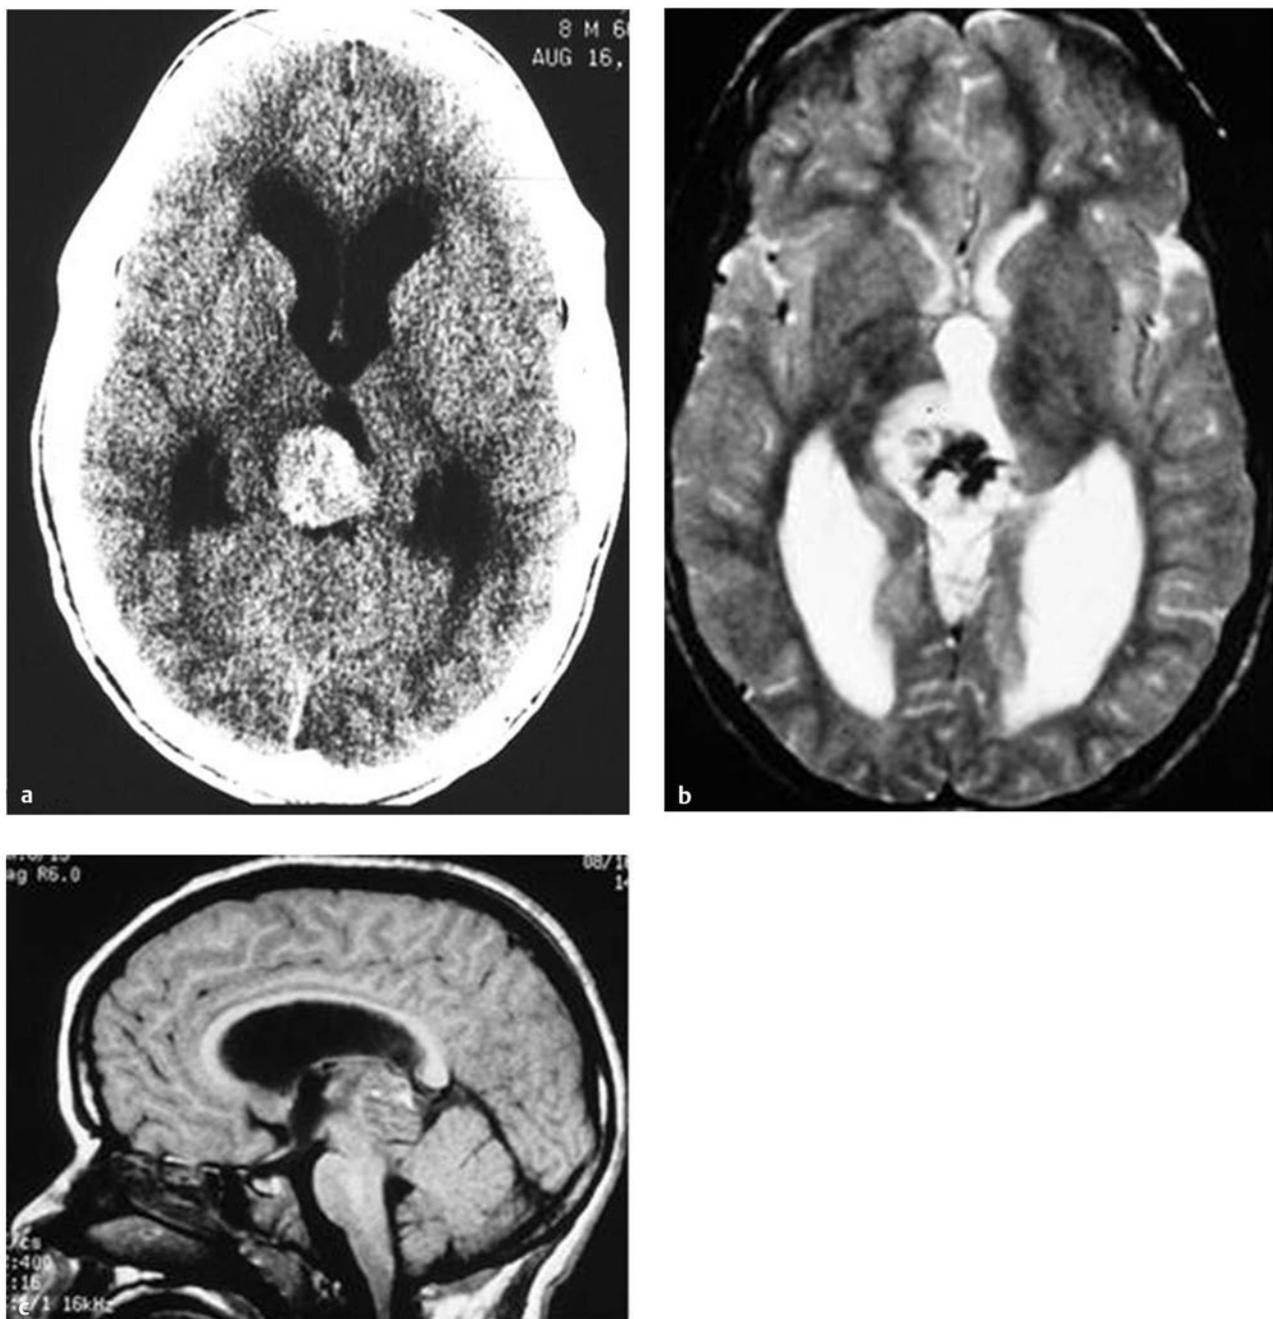

Fig. 39.3 (a) Hemorrhagic choriocarcinoma is shown on precontrast computed tomographic scan, (b) T2-weighted axial magnetic resonance (MR) image, and (c) T1-weighted sagittal MR image.

A nonenhancing thick quadrigeminal plate that causes obstructive hydrocephalus rarely requires surgical biopsy. No histologic data are available for these lesions because of the lack of pathologic verification. Contrast enhancement within the lesion may vary during follow-up despite a stable size over years. Some may show an exophytic nature, projecting beyond the quadrigeminal plate, and/or contrast enhancement, mimicking a pineal tumor.

Once a pineal region tumor is diagnosed, MR imaging of the spine needs to be obtained for staging purposes. Some malignant tumors, pineoblastomas in particular, may present with diffuse dissemination in the subarachnoid space.

39.6.2 Laboratory Tests

Certain germ cell tumors manifest tumor markers that are identified in the serum and CSF. Identification is important not only for diagnostic purposes but also for monitoring responses to treatment and relapses.³⁶ Alpha fetoprotein (AFP), a glycoprotein, is normally produced by the yolk sac and the fetal liver, but its production ceases by the time of birth. An AFP value of less than 5 ng/mL in the serum and CSF is considered to be normal.⁴⁰ In the central nervous system, yolk sac tumors (endodermal sinus tumors) show the greatest production of AFP.

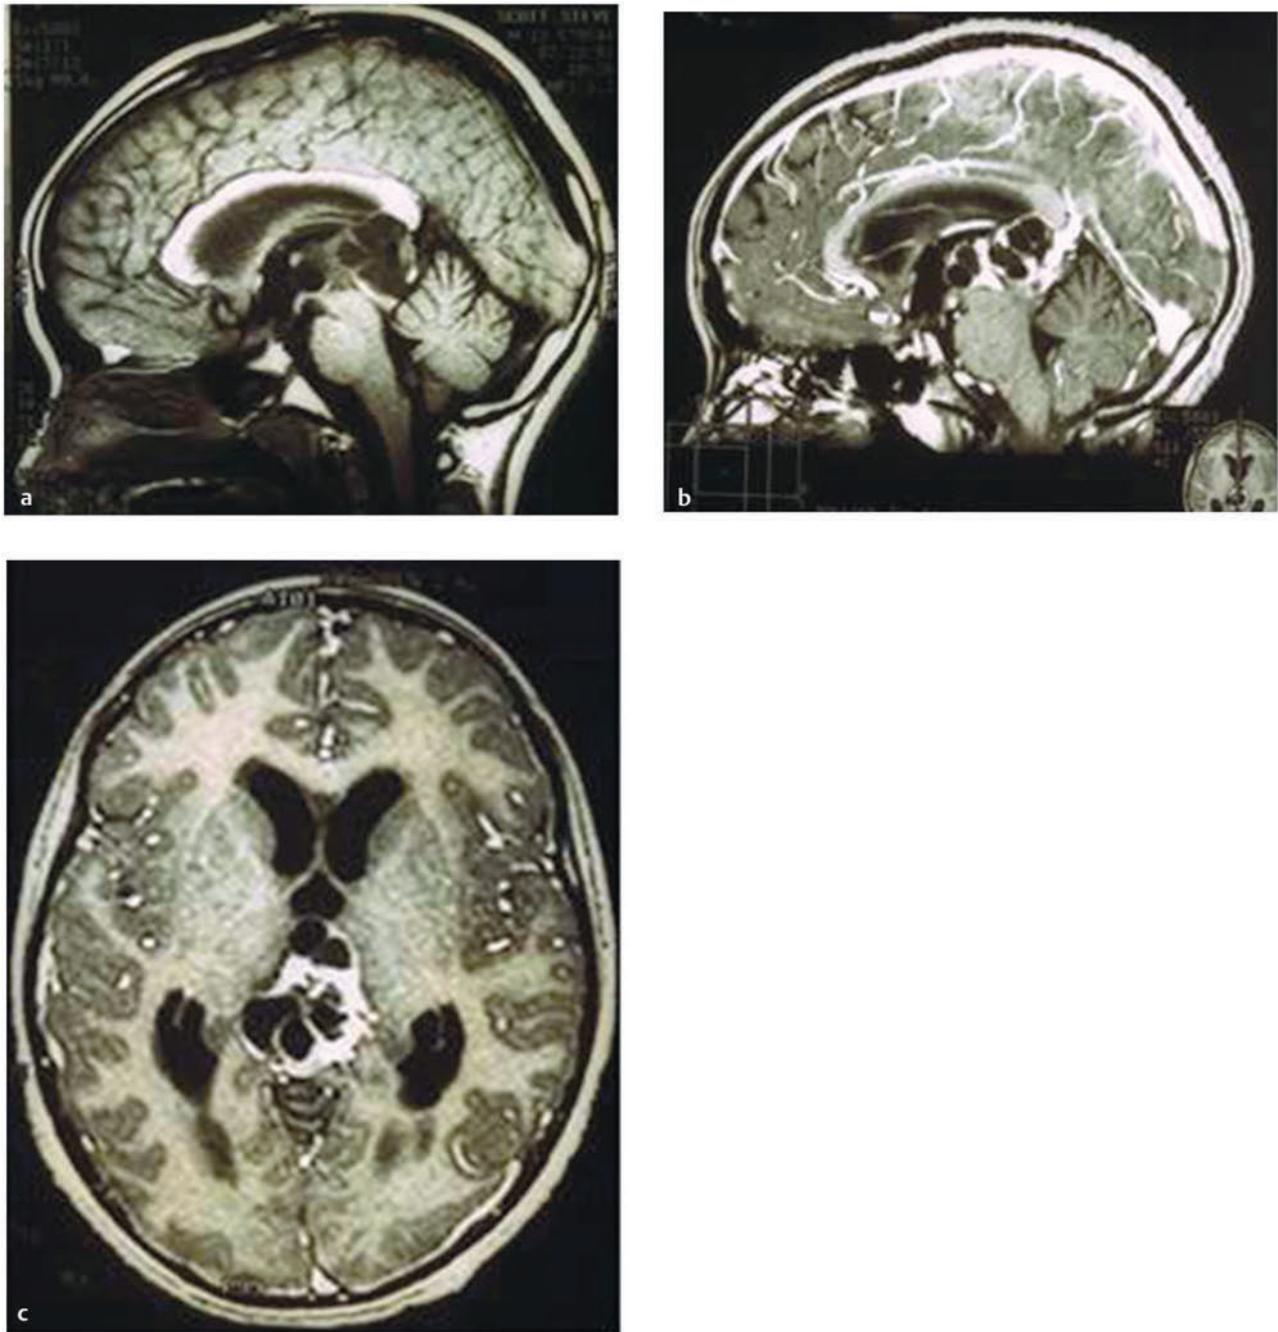

Fig. 39.4 (a) Mature teratoma is shown on precontrast sagittal magnetic resonance (MR) image. (b) Note inhomogeneous enhancement on postcontrast sagittal and (c) axial MR images.

Embryonal carcinomas and immature teratomas produce AFP to a lesser extent ($< 1,000$ ng/mL). β -HCG is a glycoprotein that is normally secreted by syncytiotrophoblastic giant cells in placental trophoblastic tissue. Therefore, the presence of β -HCG strongly indicates germ cell tumors. The normal value in the serum and CSF is less than 5 mIU/mL.⁴⁰ Marked elevation of β -HCG above 2,000 mIU/mL is noted in choriocarcinomas, but mild elevations (< 770 mIU/mL) can occur in patients with germinomas and embryonal carcinomas. The biological half-life is

about 5 days for AFP, whereas it is less than 24 hours for β -HCG. The titers of β -HCG and AFP reflect the number of cells secreting these glycoproteins; this information is useful for differentiating tumors that are predominantly choriocarcinoma or yolk sac tumor, but not confirmative for histologic diagnosis.²¹ Abnormal AFP and/or β -HCG levels in the serum or CSF are generally regarded to indicate NGGCTs.⁴²

Malignant germ cell tumors show positivity for tumor markers, either β -HCG or AFP or both, in 39 to 70% of cases.^{21,37}

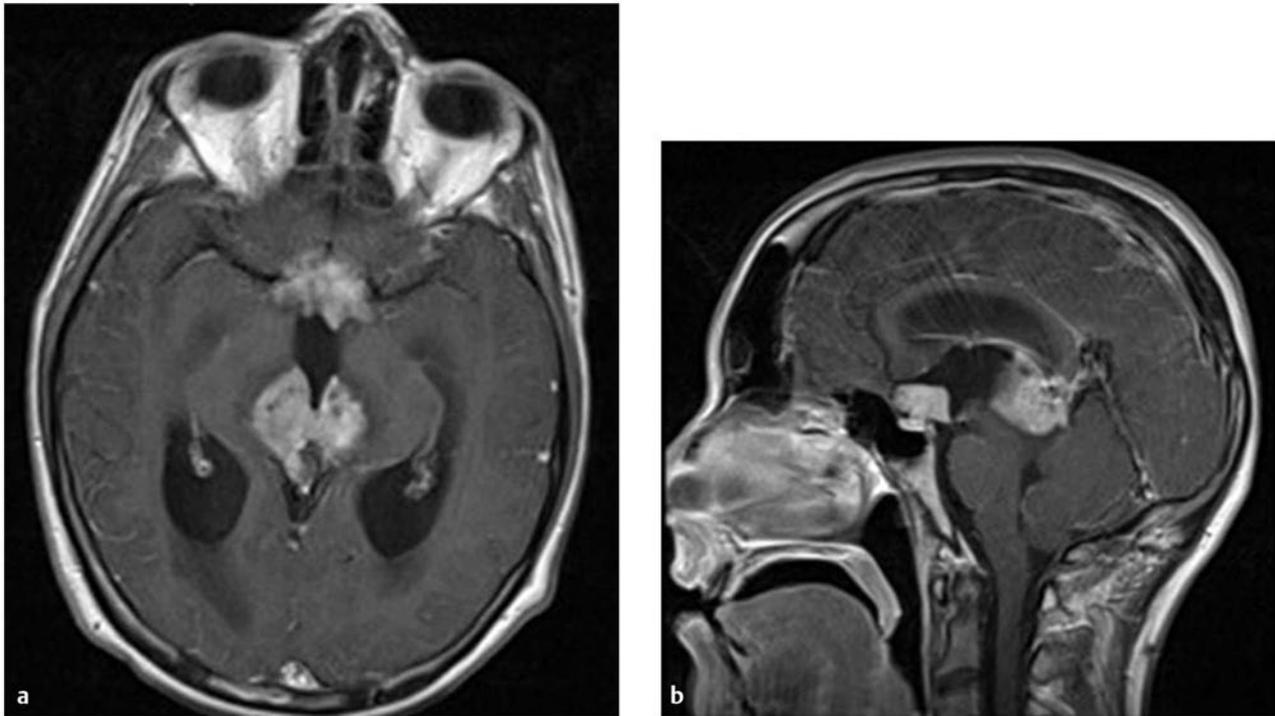

Fig. 39.5 (a) Axial and (b) sagittal magnetic resonance images after contrast infusion showing concurrent germ cell tumors with elevated serum alpha fetoprotein in the pineal and suprasellar locations.

The results of positivity for these tumor markers are variable; some report more frequent positivity for AFP⁴³ and others vice versa.⁴⁴ However, our observations (T. Tomita, unpublished data) and those of others⁴⁵ indicate that the β -HCG value tends be higher in the CSF than in the serum.⁴⁵ Thus, it is important to obtain the values of tumor markers from both serum and CSF.

Placental alkaline phosphatase (PLAP) was reported as a specific marker for primary intracranial germinomas.⁴⁶ PLAP is distinguished from other common tissue alkaline phosphatases by its heat resistance and its inhibition by L-phenylalanine. PLAP levels in serum or CSF are measured with an enzyme-linked immunosorbent assay, but their sensitivity and specificity need further investigation. The CSF in five of nine patients with germinoma showed high levels of PLAP.⁴⁷ However, reliable methods to measure PLAP in the CSF have not been available. The proto-oncogene *c-KIT*, which encodes tyrosine kinase for the stem cell factor, is expressed on the cell surface of germinoma. The concentration of the soluble form of the *c-KIT* receptor (*s-KIT*) is significantly high in the CSF among patients with germinoma.^{10,48} The melatonin level may be used as a tumor marker for pineal tumors. Melatonin secretion by the pineal gland follows a nyctohemeral rhythm. When the pineal gland is disturbed by invasive tumors such as germinoma or NGGCT, the melatonin rhythm is dramatically reduced. However, the diagnostic value of melatonin profiles is limited in clinical practice.⁴⁹ Low serum levels of melatonin may be used as a marker for pineal tumors that destroy the pineal gland.⁵⁰ High nighttime melatonin levels have been reported among patients with pineocytomas, whereas depressed melatonin secretion has been observed among patients with pineal cysts.⁵¹

39.6.3 Cerebrospinal Fluid Cytology

The CSF, whenever available, either by means of lumbar puncture or from the ventricle at shunt placement, third ventriculostomy, or external ventricular drainage, should be analyzed with cytologic studies together with tumor markers for pineal region tumors. The frequency of CSF dissemination among malignant germ cell tumors varies from 3%^{43,44} to 36 to 52%.⁵² On the other hand, pineoblastomas disseminate along the CSF pathway with higher frequencies of 50% at diagnosis and almost 100% at terminal stage.^{16,53}

39.6.4 Biopsy

Histologic verification on the basis of tumor markers and/or biopsy leads to an appropriate selection of therapeutic mode. There are several modes of biopsy: stereotactic biopsy, neuroendoscopic biopsy, and open biopsy.

Stereotactic Biopsy

Most reports indicate that the risks of surgical intervention are minimal.^{54,55} However, it is a serious potential concern that stereotactic procedures may result in hemorrhagic complications because tumors originating from the pineal gland are surrounded by deep veins of the lesser galenic system. Also, some tumors, such as pineoblastomas and choriocarcinomas, are often extremely vascular. In my experience with 14 stereotactic biopsies of pineal region tumors, two patients (one with germinoma and one with pineoblastoma) experienced a serious hemorrhage into the tumor and ventricle. However, other authors

have reported no major complications due to the stereotactic procedure.⁵⁵

Neuroendoscopic Biopsy

Neuroendoscopic tumor biopsy from the third ventricle became popular after recent advances in endoscopic instrumentation. The use of an image-guided neuronavigational system aids in localization of the tumor at endoscopic biopsy. Endoscopic biopsy can be performed at the same time as endoscopic third ventriculostomy (ETV).⁵⁶⁻⁵⁸ The pineal region tumor, however, is often difficult to visualize in the posterior third ventricle when a standard trajectory is used for the third ventriculostomy. In order to overcome this difficulty, one may use a flexible scope or a 30-degree-angle rigid scope,⁵⁷ or create another bur hole that is placed farther anteriorly.⁵⁶ Occasionally, unexpected tumor seeding may be recognized though endoscopic observation that may not be apparent on neuroimaging evaluation. Hemostasis can be achieved with a bipolar cautery. However, controlling a major hemorrhage is very difficult because of the limited field for ventriculoscopic instrumentation compounded by poor visibility due to hemorrhagic CSF. Wong et al postulated that intratumoral hemorrhage during and after endoscopic procedures for pineal tumors may be due to loose tumor tissue, hypervascularity in the tumor, and abrupt reduction in the intracranial pressure to zero during endoscopic procedures.⁵⁹ If significant hemorrhage occurs, the ventricular space should be irrigated until the returning fluid become clear. The patient may need temporary external ventricular drainage.

The tumor samples obtained with either a stereotactic procedure or ventriculoscopy are small. The pathologic diagnosis, however, can in most cases be determined from these small tumor samples. In cases of mixed malignant tumors, however,

heterogeneous components may be overlooked, and a small sample obtained with these methods may not indicate the true nature of the tumors.

39.7 Treatment

39.7.1 Hydrocephalus

Hydrocephalus may be controlled with either tumor mass reduction or a CSF diversion procedure. The surgical or nonsurgical reduction of a tumor in the pineal region would open the occluded aqueduct of Sylvius. Certain germ cell tumors can be considerably reduced in size in a short time following radiation therapy (RT) or chemotherapy, and hydrocephalus is resolved without surgery. However, these nonsurgical methods of tumor mass reduction require at least several weeks. Steroid therapy may be used for hydrocephalus pending the efficacy of RT or chemotherapy. Germinomas that contain a significant number of T-lymphocytes may be reduced in volume following steroid therapy (► Fig. 39.6).

A ventriculoperitoneal shunt was often used in the past. Placement of the shunt promptly improves the patient's condition. Concerns of the shunt, however, are potential risks for peritoneal metastases through the shunt and shunt dependency.

Recent advances in neuroendoscopic technology have enabled us to perform ETV. Successful hydrocephalus control is reported in 80% of patients with pineal region tumors.⁵⁸ The posterior third ventricle can be inspected and tumor biopsy can be performed at the same time as ETV. I routinely place an Omaya reservoir connected to the ventriculostomy catheter during the ETV that is helpful for subsequent ventricular access.

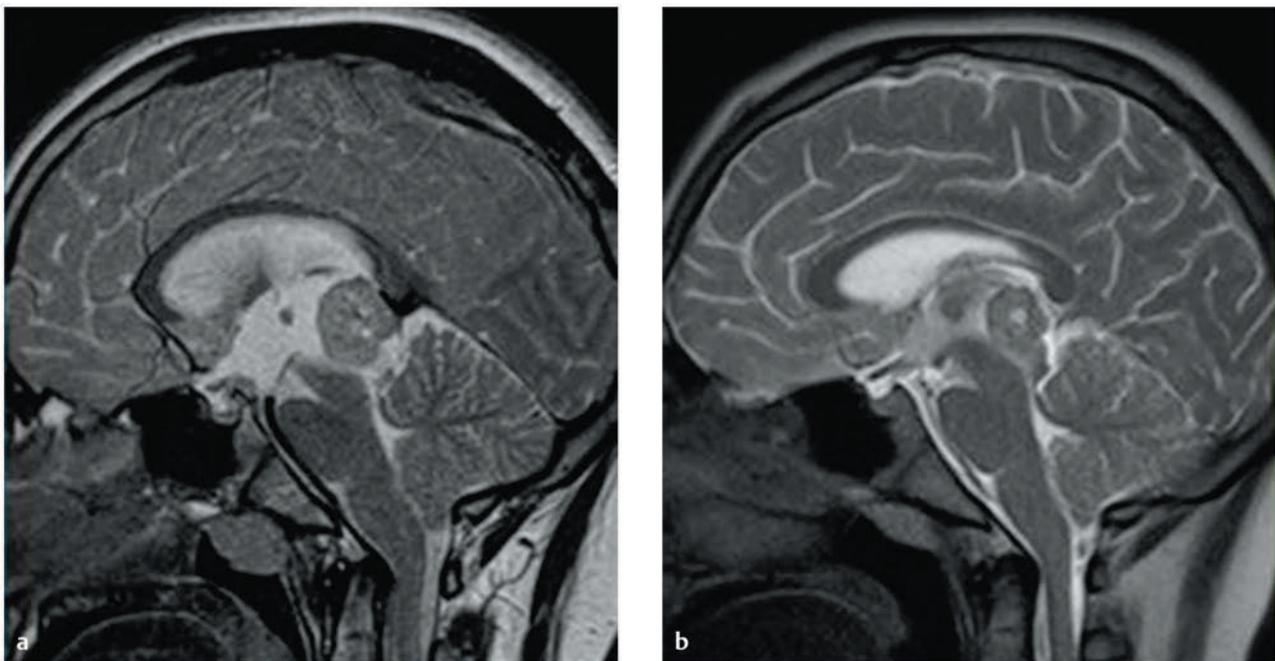

Fig. 39.6 (a) T2-weighted sagittal magnetic resonance image showing hydrocephalus secondary to pineal germinoma. (b) Following 3 days of treatment with dexamethasone, the tumor and hydrocephalus decreased in size.

39.7.2 Craniotomy

In 1921, Dandy initially described a parietal interhemispheric transcallosal approach.⁶⁰ Later, Horrax in 1937⁶¹ and subsequently Poppen in 1966⁶² developed an occipital transtentorial approach through a supratentorial craniotomy. The infratentorial route is primarily approached along the superior surface of the cerebellum and the inferior surface of the tentorium. This infratentorial supracerebellar approach was first described by Krause in 1926⁶³ and was popularized by Stein.⁶⁴

The current success in pineal tumor resections has been made possible by the surgical microscope, microsurgical instrumentation, established surgical approaches, and advanced neuroimaging studies. Intraoperative imaging guidance is also helpful. Approaches are either supratentorial or infratentorial.⁶⁵ The supratentorial routes include an occipital transtentorial approach, posterior interhemispheric approach, posterior interhemispheric transcallosal approach, anterior interhemispheric transcallosal approach, and lateral transventricular approach.

Each approach has advantages and disadvantages, and the approach should be chosen on the basis of the anatomical information provided by neurodiagnostic images, along with the surgeon's familiarity with and confidence in using the approach. The tumor location and extent, the deep venous system, and the surrounding neural structures need to be considered when the surgical approach is chosen. Other factors are the patient's age, presence or absence of hydrocephalus, shape of the head, and purpose of the surgery (biopsy vs. total resection). I personally prefer the supratentorial approach because pineal region tumors in children tend to be large and extend in various directions, and also because the posterior fossa space in infants and children is relatively small. The supratentorial approach provides a wide range of trajectory angles through a large interhemispheric avenue.

Supratentorial Approach

Occipital Transtentorial Approach

The prone position is used routinely, although some prefer a sitting position. I personally prefer to place all pediatric patients in a prone position with the head turned slightly (about 15 degrees) away from the surgical side if the patient is old enough to receive head pins for a head holder. This position is designed to let gravity cause the occipital lobe fall away from the falx, without the need for forcible brain retraction. Some choose a recumbent position for that reason.⁶⁶ If the patient is very young, when a pin fixation device is not applicable, the head is rested on a well-padded horseshoe head holder; the head is not turned. Brain retraction is controlled by means of intraoperative ventricular drainage for the interhemispheric approach. Retraction of the occipital and parietal lobes is more restricted when the ventricle is small or slitlike. One should avoid forcible retraction of the occipital lobe. The brain needs to be relaxed with the administration of mannitol, or sometimes by externalizing an existing shunt intraoperatively.

The occipital transtentorial approach provides a wide surgical entry for access to the pineal region. One can select from a wide range of angles of entry through a craniotomy that extends from the inion to the entry site of the last cortical vein into the superior sagittal sinus, which is usually 3 to 5 cm rostral to the

lambda. Exposure of the lateral sinus is not necessary because the approach is not suboccipital (lifting the occipital lobe) but through the interhemispheric fissure along the falx. Through a hockey stick skin incision (► Fig. 39.7), a craniotomy is usually placed that is approximately 10 cm in length and 5 cm in width and crosses over the superior sagittal sinus to the opposite side (► Fig. 39.8). At the entry of the interhemispheric fissure, there usually are no cortical veins posterior to the posterior parietal region. In my experience with 68 posterior interhemispheric approaches, only one patient had a significant draining vein from the occipital pole. However, Davidson et al stated that 7 of 27 patients needed bridging vein sacrifice through this approach.⁶⁶

Once the posterior interhemispheric fissure is entered along the falx, the splenium of the corpus callosum, the straight sinus, and the ipsilateral tentorium are in the surgical view (► Fig. 39.9a). The ipsilateral tentorium is sectioned approximately 1 cm lateral to the straight sinus in a length of 2 to 3 cm, exposing the underlying superior vermis (► Fig. 39.9b). This approach provides the surgeon with adequate exposure that ranges from the upper posterior fossa caudally and the anterior portion of the third ventricle rostrally. The vein of Galen is overlying the tumor when approached from the occipital and posterior parietal regions (► Fig. 39.9c). The microscope trajectory needs to be adjusted to a more horizontal angle to separate the dorsal surface of the tumor from the vein of Galen and its tributaries and to further visualize deep into the third ventricle. The only difficult area to expose is the opposite side beyond the falx. The contralateral portion of the tumor is brought into the surgical view by gradually retracting the tumor capsule following

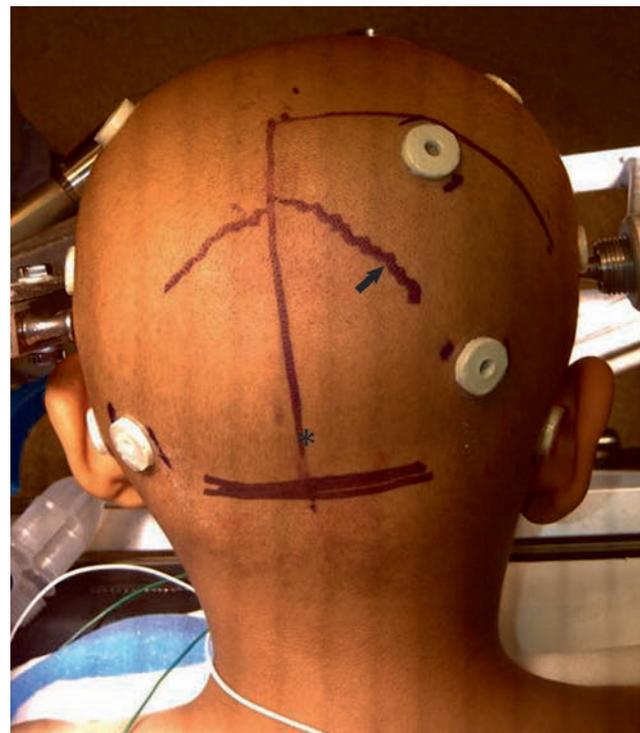

Fig. 39.7 Hockey stick skin incision for a right-sided occipital craniotomy and an occipital transtentorial approach. Note the right-sided lambdoid suture (arrow) and the inion (asterisk).

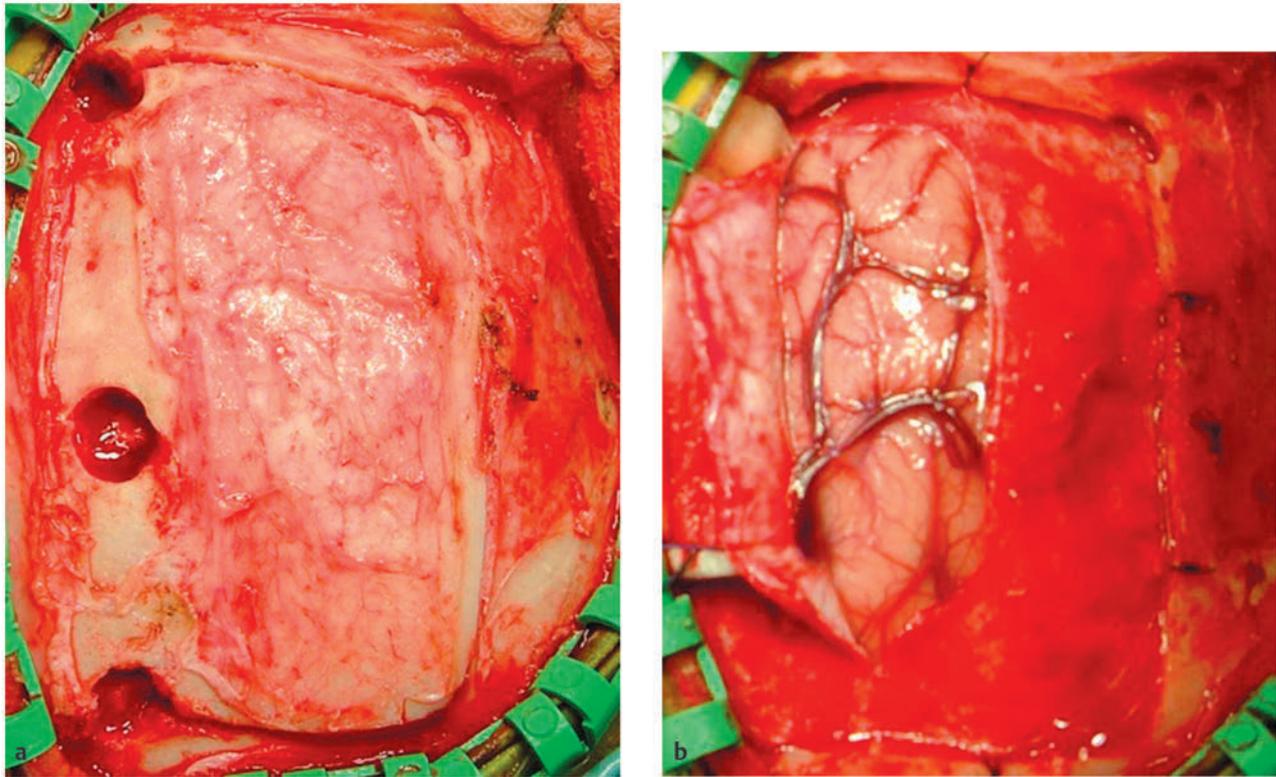

Fig. 39.8 A left occipital craniotomy for the occipital transtentorial approach is shown. (a) Bur holes are placed, one at 3 cm above, another just at the lambda, and the third one above the inion in the midsagittal plane. (b) A craniotomy extending beyond the midline is lifted.

internal decompression and reduction of the tumor bulk. The intraoperative use of a neuroendoscope is helpful to inspect this area and enhance the resectability.⁶⁷

When the microscope trajectory is adjusted vertically, the posterior surface of the tumor and the superior vermis are visualized through the sectioned tentorium. A large exposure in the upper posterior fossa, the quadrigeminal plate, the superior medullary velum, and the superior vermis is attained. A pineal region tumor that extends through the superior medullary velum to the fourth ventricle can be removed with this approach. For resection of a tumor in the anterior portion of the third ventricle, one can adjust the surgical microscope trajectory to angle horizontally. Following a successful tumor resection, the structures of the anterior wall of the third ventricle are within the surgical view (► Fig. 39.10). Sectioning of the splenium of the corpus callosum is rarely necessary. However, it may be necessary for resection of a massive tumor of the third ventricle, or if the space between the quadrigeminal plate and the vein of Galen is too tight to allow entry into the third ventricle. If the tumor originates from the posterior thalamus or is growing into the atrium of the lateral ventricle, the retrosplenial parahippocampal gyrus is retracted farther laterally.

Anterior Transcallosal Approach

Although some contend that sacrificing the middle third of the superior sagittal sinus cortical bridging veins does not cause permanent deficits,⁶⁸ others recommend using an anterior interhemispheric transcallosal approach, minimizing the risks for

venous infarct of the motor centers.⁶⁹ The patient is placed in a supine position with the head in the neutral position. The craniotomy is placed 4 to 5 cm anterior and 1 to 2 cm posterior to the coronal suture, crossing the midline. The ipsilateral anterior interhemispheric fissure is entered after one or two bridging veins are coagulated and sectioned, which usually is not of clinical significance. The corpus callosum is sectioned about 2 cm at its anterior body, which allows exposure of the ipsilateral lateral ventricle.

When the third ventricle is totally occupied by a large tumor that extends farther into the lateral ventricle, either through the foramen of Monro or beneath the tela choroidea, an anterior interhemispheric transcallosal approach is preferable through a posterior frontal craniotomy. This approach allows the surgeon to resect the tumor through the subchoroidal route. Because the tumor mass is already lifting the roof of the third ventricle, the subchoroidal space is stretched and widened in the medial wall of the lateral ventricle, and one can readily reach the entire third ventricular space through the subchoroidal space.

A transcallosal interforniceal approach through an anterior interhemispheric approach has been advocated recently for pineal region tumors.⁶⁹ Through a unilateral frontal craniotomy and interhemispheric approach, the anterior corpus callosum is sectioned about 2 cm. The interforniceal space is separated just above the foramen of Monro and then posteriorly. It is important to stay strictly on the midline by identifying the attachment of the septum pellucidum to the fornices. If one can enter the cavum septi pellucidi, the separation of the interforniceal space is less laborious. Through the space between the internal

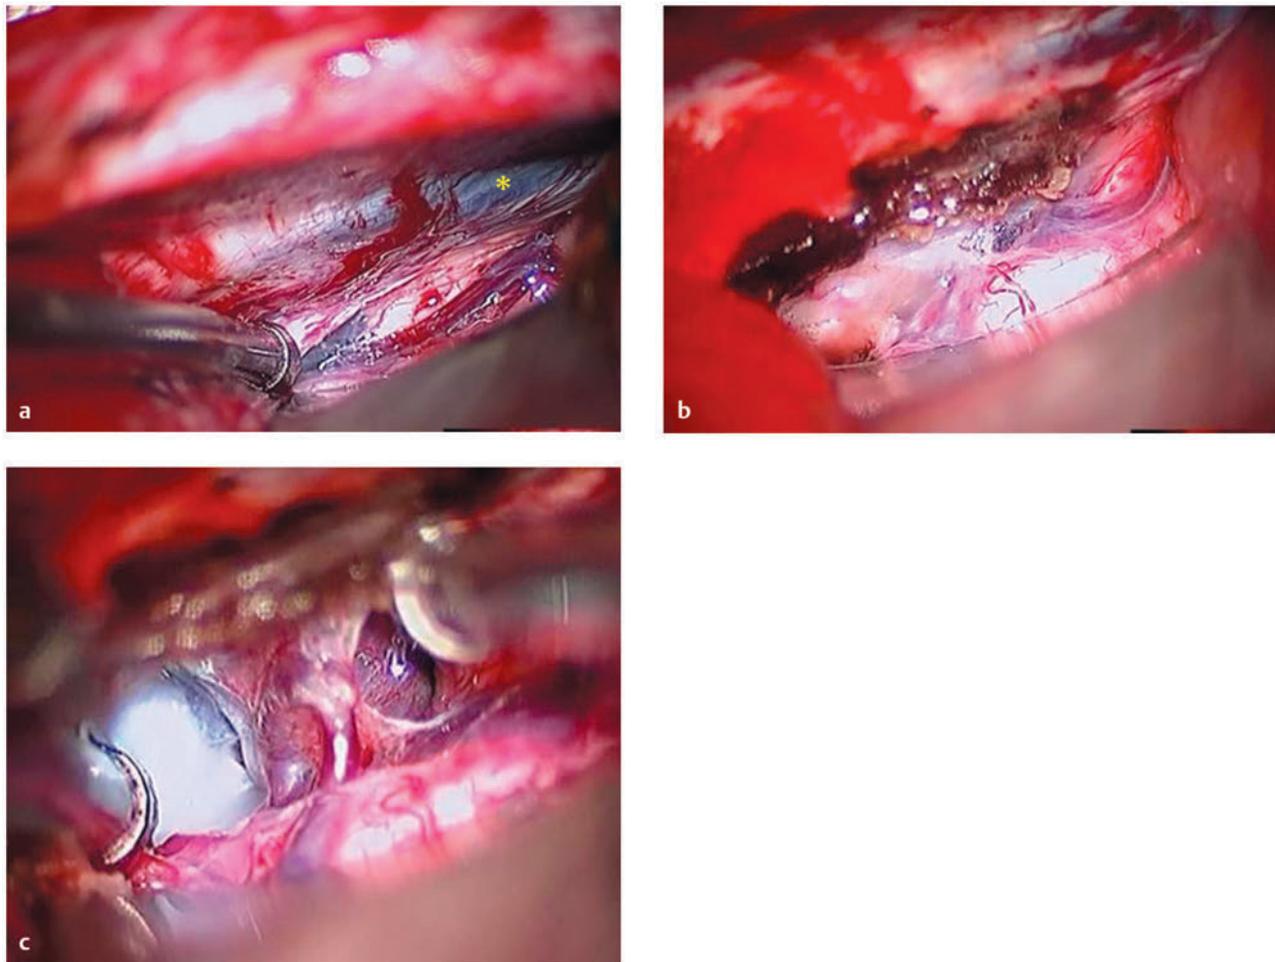

Fig. 39.9 An intraoperative photograph showing the posterior interhemispheric approach. (a) Note the posterior falx, the straight sinus (*asterisk*), and the tentorium, with partial exposure of the splenium of the corpus callosum. (b) The tentorium is sectioned, and the pineal region is in surgical view. (c) Following the opening of the arachnoid membrane of the quadrigeminal cistern, the vein of Galen and the tumor capsule are visible.

cerebral veins in the tela choroidea, the third ventricle is entered. It is necessary to section the massa intermedia to visualize the posterior third ventricle mass. Jia et al reported a high success rate of gross total resection of pineal region tumors in children when they used this approach. However, they had a high incidence of postoperative short-term memory deficit in 94 of 150 patients, although the memory deficits were usually transient and resolved within 6 months.⁶⁹

Infratentorial Approach

Infratentorial Supracerebellar Approach

Through a midline posterior fossa craniotomy, both lateral sinuses should be in the surgical field. The several superior vermian veins need to be sectioned along with the precentral vein to access the pineal location. The superior vermis is depressed, and the microscope trajectory is adjusted to avoid injuring the vein of Galen. The advantage of this approach is the midline trajectory, approaching the center of the tumor between the cerebellum and tentorial opening. The deep venous system is above and to the side of the tumor; thus, it is not disturbed during tumor resection. If a sitting position is used, gravity works in the

surgeon's favor because the tumor falls away from the galenic system above, minimal force is required for cerebellar retraction, and the surgical field is dry because blood and CSF are drained out by gravity. If the tumor is above the galenic system, however, it is difficult to remove it through this approach.

A concern with the use of the sitting position is the development of air embolism and hypotension. Young children, who cannot tolerate head pins for fixation, are difficult to place in the sitting position. When a sitting position is used, associated hydrocephalus needs to be decompressed before craniotomy. Otherwise, gravity will force the CSF out from the open third ventricle, which can result in acute collapse of the ventricular system and subdural hematoma or pneumocephalus. For the infratentorial supracerebellar approach, some surgeons prefer the Concorde (modified prone) position to avoid the sitting position.⁷⁰

In infants and young children, the posterior fossa is small and the distance from the foramen magnum to the torcular Herophili may be only 3.5 to 4.0 cm. Some older children or adults, particularly those with a flat occiput, may have a low-setting torcular Herophili. In these anatomical conditions, the surgical field through a supracerebellar approach is often restricted.

Depressing the cerebellum to expand the surgical opening and sectioning the vermian veins can result in postoperative cerebellar swelling. Particularly the portion of the tumor in the region of the superior medullary velum requires further depression of the superior vermis. It is difficult to remove tumors

located above the deep venous system or laterally beyond the tentorial opening, or extending into the lateral ventricle. More recent authors advocate an endoscopically controlled resection of pineal lesions through an infratentorial supracerebellar approach.⁷¹

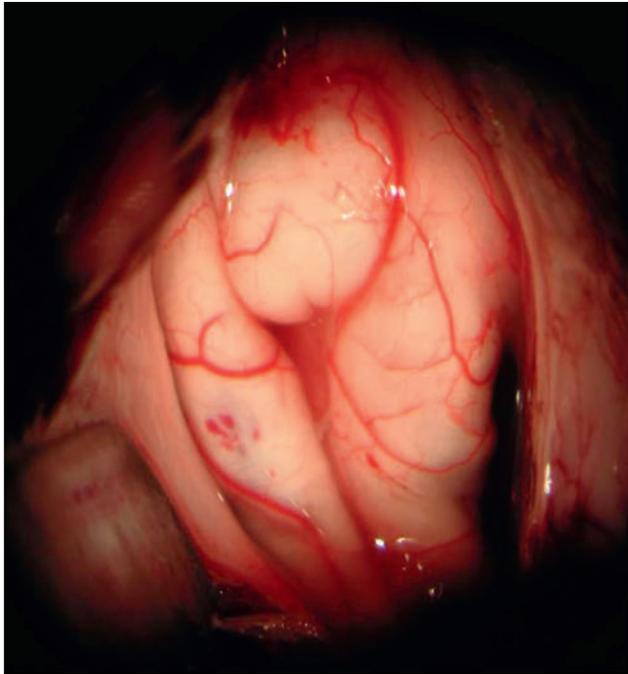

Fig. 39.10 Intraoperative photograph showing the anterior third ventricle following the tumor resection. Note the column of the fornix on each side, with the anterior commissure (*asterisk*).

39.7.3 Tumor Resection

The quadrigeminal cistern has a thick arachnoid membrane. Once the arachnoid membrane is opened, pineal tumors are exposed in the quadrigeminal cistern under the vein of Galen. Glial tumors may be covered by a thin cortex of either the quadrigeminal plate or the posterior thalamus. In such a case, one may identify a grayish pineal gland in the vicinity of the tumor. Pineal germinomas are well encapsulated, granular, and fibrous. Teratomas have a distinct capsule that often contains multiple cysts with light to thick mucoid contents. The inner structures of most teratomas are firm, and some are too fibrous and rubbery to aspirate by means of an ultrasonic aspirator. A tedious piecemeal resection is needed. In such a case, a surgical laser is quite helpful. Choriocarcinomas and yolk sac tumors are vascular, yet encapsulated. Old blood clot may be present within the tumor. Some tumors are extremely vascular, and one may need to terminate further surgical resection. Pineoblastomas are mostly soft and necrotic. They can often be suctioned away, but they are frequently very vascular because of tumor neovascularization.

Astrocytomas of the quadrigeminal plate or of thalamic origin are also resectable. On opening the quadrigeminal cistern, one should stay in the midline above the superior colliculi or identify the exophytic portion to debulk the mass. One should avoid traumatizing the inferior colliculi to prevent postoperative hearing loss. Thalamic astrocytomas may be approached

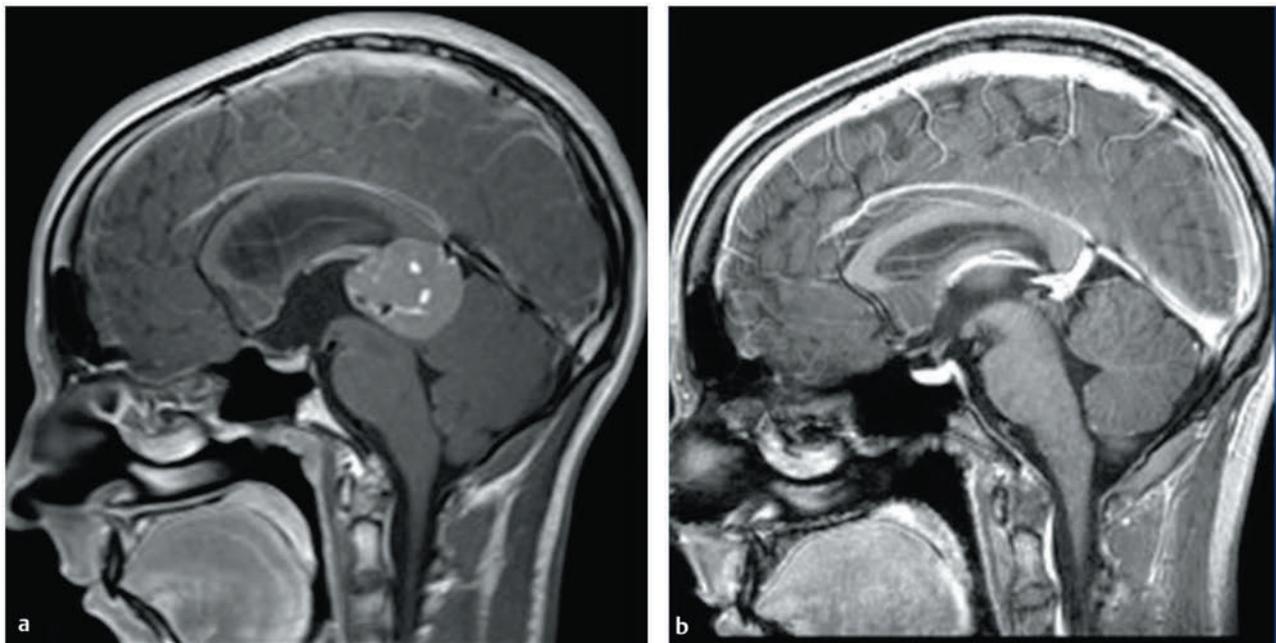

Fig. 39.11 Postcontrast sagittal magnetic resonance image of biopsy-proven germinoma (a) before and (b) 3 months after two cycles of chemotherapy. Note the rapid response of the tumor to the chemotherapy.

through the quadrigeminal cistern when the pulvinar is primarily involved. Benign astrocytomas are often well demarcated, and a gross resection is possible if one chooses the appropriate surgical approach.

39.7.4 Surgical Complications

In recent studies, surgical mortality is nearly zero. With an occipital transtentorial approach, retraction of the occipital lobe can cause hemianopia, although this is almost always transient.⁷² Retraction of the cerebellum together with sectioning of the superior vermian veins may result in postoperative cerebellar swelling following the infratentorial supracerebellar approach. Manipulation of the quadrigeminal plate and the posterior commissure may result in persistent or worsened Parinaud syndrome. This is due not only to mechanical manipulation but also to vascular disruption of the quadrigeminal plate at the tumor resection. Postoperative neurologic deterioration may be due to hemorrhage in the tumor resection cavity or other intracranial compartment, cerebral or cerebellar swelling, or acute hydrocephalus. When the third ventricle is manipulated, one should carefully monitor the serum sodium level and urinary output to detect an inappropriate secretion of antidiuretic hormone or diabetes insipidus.

The true frequency of venous infarcts in the thalamus and basal ganglia secondary to surgical occlusion of the vein of Galen or its tributaries is not known. It is known that there is extensive collateral circulation in the vein of Galen and its tributaries. The consequences of surgical occlusion of the galenic system may have been overstated,^{66,73} but one should try to preserve these deep veins. Intraoperative hemorrhage from the vein of Galen is usually controlled by the application of hemostatic agents and gentle compression with a cottonoid.

39.8 Adjuvant Therapies

39.8.1 Germ Cell Tumors

Among germ cell tumors, teratomas, either mature or immature, necessitate surgical removal because of their lack of response to adjuvant therapy. Once a mature teratoma is removed, the cure rate is extremely high without further therapy. Other tumors (germinomas and NGGCTs), however, need further therapy. They have shown sensitivity to RT and chemotherapy, and these adjuvant therapies have become the primary form of the treatment.

Irradiation

The radiosensitivity of germinomas has been well recognized. Total eradication of the tumor can be achieved with only 1,600 cGy of radiation.⁷⁴ After treatment with RT alone for biopsy-proven pineal germinomas, the rate of 5- to 15-year disease-free survival is 80 to 100%.^{21,43,44,75,76}

The doses of irradiation for pineal germinomas have been controversial. The doses of irradiation to the brain for germinomas generally range from 5,000 to 5,500 cGy in the literature.⁷⁷ Some authors contend that the dose should be lowered for this radiosensitive tumor. Comparative disease-free survival rates were achieved with a dose to the primary tumor site of less

than 4,800 cGy,^{78,79} while others report that even in patients with multifocal germinomas treated with 3,000 cGy to the whole ventricle, tumor control was excellent.⁸⁰

The question of whether the field of irradiation should be limited to the primary tumor site and its margin^{77,79} or should include the whole brain or ventricle^{21,31,76,80} or the craniospinal axis^{43,81} has been controversial. Some recommend stereotactic irradiation or brachytherapy because these conformal irradiation techniques would improve efficacy and reduce radiation risks.⁸² The reported incidence of CSF dissemination of intracranial germinomas in the literature range from 10⁸ to 52%.⁵² For localized germinomas, it is accepted that irradiation should be applied to the whole ventricle or to the craniospinal axis when there is evidence of CSF dissemination.^{52,77,83} Lafay-Cousin et al attained excellent responses in bifocal germinomas with chemotherapy followed by whole-ventricle RT.⁸⁴ The risk for recurrence of germinomas in the leptomeninges without prior irradiation to the spine is in the range of 6 to 20%,^{21,76,85} whereas Wolden et al reported the spine-only failure rate to be only 2%.⁴⁴ In the previous trial (Children's Oncology Group [COG] ACNS0232), germinomas were treated with 2,100 cGy to the whole ventricle and a 2,400-cGy boost to the primary site; the radiation dose to the primary site was decreased to 3,000 cGy when neoadjuvant chemotherapy was used, and a complete response was attained. In a current clinical trial in the United States (COG ACNS1123), patients with pure germinomas receive 1,800 cGy to the whole ventricle with a 1,200-cGy boost to the tumor bed following chemotherapy if they are complete responders; patients with a partial response receive 2,400 cGy to the whole ventricle and a 1,200-cGy boost to measurable disease sites.

The younger the patient and the greater the dose and field of the irradiation, the greater the sequelae of ionizing irradiation to the developing central nervous system. Intellectual retardation and endocrine dysfunction are relatively common sequelae, occurring in approximately 25%, after irradiation for pineal germinomas in childhood.⁸⁶ However, Merchant et al reported no significant differences between the pre- and postirradiation IQs of children with intracranial germinomas who received craniospinal axis irradiation with a median dose of 2,560 cGy.⁸¹

Despite their high sensitivity to radiation, about 10% of germinomas show recurrence. Relapse may be due to an inadequate initial radiation field, the growth of a radiation-resistant tumor component, such as teratoma or NGGCT, or shunt-related extraneural metastases.⁸⁷ Among germinomas, those associated with an elevated β -HCG level (>50 IU/L) may be less sensitive to radiation than pure germinomas.^{21,88}

Contrary to the successful results of RT in germinomas, the response to RT alone in NGGCTs has been poor. The 5-year survival rate after RT ranges from 10 to 27%²¹ to 60%.⁴⁴ The Japanese Intracranial Germ Cell Tumors Study Group reported a median survival time of 18 months and a rate of CSF dissemination or hematogenous dissemination of 45% among patients with NGGCTs.²¹ The same report showed that patients who had pure choriocarcinoma, yolk sac tumor, or embryonal cell carcinoma had a 5-year survival rate of 9.3%, whereas patients who had germinomas mixed with elevated β -HCG or teratoma, immature teratoma, or mixed tumors consisting predominantly of germinoma or teratoma had a 5-year survival rate of 70%. A few centers reported the value of radiosurgery for malignant germ

cell tumors. There were diverse responses to radiosurgery among patients with malignant germ cell tumors.^{89,90}

Chemotherapy

The sensitivity of germ cell tumors to chemotherapy has been well recognized. Allen et al⁹¹ and Kobayashi et al⁹² reported a high response rate among germ cell tumors to neoadjuvant multiple-agent chemotherapy. Subsequently, multiple reports indicated high response rates of malignant germ cell tumors to neoadjuvant chemotherapy.^{75,93,94} In 1994, Allen et al reported a 100% response rate of germinomas to single-agent chemotherapy with carboplatin in 10 patients.⁹⁵

A European prospective study using multiple-agent chemotherapy in 1996 showed high response rates among both germinomas and NGGCTs. The rates of complete response to the chemotherapy did not differ between the germinoma group (84%) and the NGGCT group (78%).⁴⁰ Also, the Japanese Pediatric Brain Tumor Study Group reported in 2001 similarly high rates of responses among germinomas following multiple-agent chemotherapy consisting of etoposide with carboplatin or cisplatin.⁹⁶ Complete response rates were 83.6% among patients with germinoma and 77.8% among those with germinoma with syncytiotrophoblastic giant cells, whereas patients with NGGCT showed no or limited responses.⁹⁶

However, despite the high early response rates, both studies reported that subsequent follow-up without RT showed high rates of recurrence. The European study showed recurrences in 28 (51%) of the 55 patients with a complete response to neoadjuvant chemotherapy, which occurred between 8 and 49 months.⁴⁰ In this study, age of the patient, tumor location, presence of CSF dissemination, extent of tumor resection, and positivity for tumor markers did not influence outcome. However, a statistically significant difference was noted between the pathologic types: the 5-year survival rates were 84% for the germinoma group and 62% for the NGGCT group.

Similarly, the Japanese study showed a 50% recurrence rate within 1.5 years among patients with germinomas who had an initial complete response.⁹⁶ Most recurrences in the European study were treated with a combination of RT and chemotherapy. Notably, all 10 patients who received cyclophosphamide for recurrence showed a complete response. Although 10% (7 of 71 patients) died of the toxic effects of chemotherapy, this study clearly showed the chemosensitivity of these tumors, resulting in at least short-term remission.

A COG protocol (ACNS0122) treated NGGCTs with neoadjuvant chemotherapy, with the diagnosis confirmed based upon the results of testing for tumor markers or biopsy. Following two to three cycles of chemotherapy and an evaluation of the responses of the tumor markers or the responses on neuroimaging, second-look surgery was recommended if there was any concern for residual tumors. At second-look surgery, tumors resistant to radiation, such as mature or immature teratomas, may be encountered. These teratomas are also chemoresistant and may continue to grow during or after chemotherapy. Growing teratomas require surgical resection.⁹⁷ These patients subsequently received RT with 5,400 cGy to the tumor sites and 3,600 cGy to the craniospinal axis. Craniospinal irradiation remains controversial. In the latest

COG protocol (ACNS1123) for localized germ cell tumors, patients receive 3,060 cGy to the whole ventricle and a 2,340-cGy boost to the primary tumor site if the tumors respond to chemotherapy.

Chemotherapy is effective not only for primary tumors but also for disseminated germinomas. In patients who received a CSF diversion shunt for malignant germ cell tumor, chemotherapy would effectively reduce the possibility of peritoneal spread of the tumor cells.

A high response rate of NGGCTs after multiple-agent chemotherapy has been reported.⁹⁸ In a recent report from the COG regarding the use of multiple-agent induction chemotherapy among children with NGGCTs (COG ACNS0122), 32% achieved a complete response and 21.5% achieved a partial response (S. Goldman, personal communication, 2012). Certain malignant NGGCTs are extremely vascular. These tumors can be treated initially with chemotherapy, which not only reduces the size of the mass but also reduces the vascularity of the tumor. Second-look surgery for residual tumor after neoadjuvant chemotherapy is recommended before further treatment.⁴⁰ The residual tissues resected at second-look surgery after chemotherapy are often resistant to radiation, such as teratoma or necrotic tissue without viable tumor cells.⁹⁹ Of the 19 patients treated in COG ACNS0122, 13 were found to have teratomas, 4 fibrosis, and 4 persistent NGGCT. Paradoxical acceleration of the growth of mature teratomas (growing teratoma syndrome) may occur following neoadjuvant chemotherapy.^{97,100} The dose and field of irradiation may be reduced following chemotherapy.^{21,101} A combination with chemotherapy and a reduced dose of irradiation with local fields showed increased cure rates and reduced radiation-induced side effects, including anterior pituitary dysfunction.^{101–103}

39.8.2 Pineal Parenchymal Tumors

Pineoblastomas frequently affect infants and young children. They tend to recur and disseminate without appropriate therapy.^{4,10,16,53} Pineocytomas, however, are considered to be benign, and surgical excision can lead to a cure of affected patients.¹⁰⁵

Patients with pineoblastoma are treated with adjuvant therapy. For very young children, postoperative adjuvant chemotherapy was used in both a Pediatric Oncology Group (POG) and a Children's Cancer Group (CCG) study. The former included 11 patients younger than 3 years who received combination chemotherapy ("Baby POG") with cyclophosphamide, vincristine, cisplatin, and etoposide.⁵³ None of these children underwent gross total resection of tumor. All children ultimately failed chemotherapy between 2 and 11 months. The sites of relapse were frequently in the primary pineal location and in the CSF. No patient with leptomeningeal spread responded to chemotherapy. The CCG treated eight infants younger than 18 months of age at diagnosis with an eight-drugs-in-one-day (8-in-1) chemotherapy regimen.¹⁰⁶ All patients showed progressive disease at a median of 4 months from the start of treatment. Mandera et al treated 10 children with pineoblastoma with resection and chemotherapy and reported a mean survival time of 24.7 months and a 3-year survival rate of only 36%.^{2,6} On the other hand, the group of patients who were older than 18 months

of age and received craniospinal RT and chemotherapy had better survival. These patients had a 3-year progression-free survival rate of 61%, which was better than that for children with other supratentorial PNETs. According to Ashley et al, children with pineoblastoma responded to some degree to postoperative high-dose cyclophosphamide therapy.¹⁰⁷ However, cyclophosphamide therapy for recurrent pineoblastomas was not effective. A report from Duke University on the use of high-dose chemotherapy with autologous stem cell rescue followed by RT showed promising survival data, with 4-year progression-free and overall survival rates of 69% and 71%, respectively.¹⁰⁸

The value of aggressive total resection of pineoblastoma remains an enigma. Some recommend no further resection once biopsy confirms pineoblastoma.¹⁰⁶ Anecdotal long-term survival after biopsy and RT was reported.^{109,110} Gross total resection of other PNETs, medulloblastomas in particular, has been considered to provide better patient outcome. However, despite similar therapeutic modality, the prognosis of children with pineoblastoma and other supratentorial PNETs remains worse than the prognosis for those with medulloblastoma.¹¹¹ The extent of tumor resection may show a trend toward an association with outcome, with better survival following maximum tumor resection than after partial resection, but it did not show statistical differences in patient outcome.^{16,106}

Pineocytomas with a pineoblastic component are regarded as malignant and treated accordingly. However, pineocytomas are in general considered to be benign and rarely disseminate.¹⁴ Mandera et al reported that only 2 of 16 children with pineocytoma had recurrence after resection alone.^{2,6} However, some authors consider pineocytoma a malignant tumor and recommend RT,^{112,113} whereas others doubt the effects of RT on pineocytomas.¹¹⁰ The lack of responsiveness to radiation was noted by Vaquero et al, who observed that pineocytomas show little or no response to so-called diagnostic RT at a dose of 2,000 cGy.¹¹⁴ However, radiosurgery is considered to be more effective, and Hasegawa et al reported a 100% local control rate.¹¹⁵ None of the patients reported by Vaquero et al had tumor recurrence after surgical resection without further adjuvant therapy.

39.8.3 Astrocytomas

Benign astrocytomas in the pineal region arise in the quadrigeminal plate, tegmentum of the midbrain, or posterior thalamus. Superior vermian astrocytomas may extend to the pineal region, and advanced neuroimaging studies disclose the origin of the tumor. A majority are juvenile pilocytic astrocytomas. They are often well demarcated but do not possess an obvious tumor capsule. However, direct surgical resection may be associated with postoperative morbidity.

Astrocytomas of the quadrigeminal plate usually present with indolent progression. They are often managed with CSF diversion alone.¹¹⁶⁻¹¹⁸ Progression of disease characterized by enlargement of the tumor was noted in 25% of patients during follow-up after placement of a CSF diversion shunt. When disease progression occurs, biopsy (open or

stereotactic) followed by local irradiation provides long-term survival.¹¹⁶

39.9 Management Protocols

Neuroimaging studies, both CT and MR imaging, should be carefully reviewed and their findings correlated with patient's age, sex, presenting symptoms, and tumor markers. The presence or absence of hydrocephalus should be determined. If hydrocephalus is the presenting sign, immediate medical attention is needed. Placement of a ventriculoperitoneal shunt is avoided if possible because of concerns about CSF seeding and the development of shunt dependency and slit ventricles. One option is ETV (with CSF for tumor markers and cytology obtained at the same time), and another is craniotomy with tumor resection to restore the CSF pathway.

39.9.1 Tumors of the Pineal Gland

In children and adolescents with pineal region tumors, the serum and CSF should be evaluated for tumor markers (AFP and β -HCG) to rule out NGGCT. Neuroimaging studies often enable the differentiation of pineal teratomas (mature or immature) from other tumors because of their distinct characteristic appearance. Neuroimaging studies are also often diagnostic for pineal germinomas in male teenagers when testing is negative for tumor markers. When testing for tumor markers is negative, surgical biopsy is indicated. Neuroendoscopic biopsy at the time of ETV has become widely accepted. When testing for tumor markers is positive, neoadjuvant chemotherapy is recommended without surgical biopsy. After initial chemotherapy, it is advised that these patients undergo a second-look operation for radiographically defined residual tumor. After the second-look operation, RT is applied depending on the results of histologic examination and testing for tumor markers. Solid double tumors in both the anterior and posterior third ventricle are considered to be malignant germ cell tumors (germinomas if the testing for markers is negative, otherwise NGGCT) and require chemotherapy followed by RT.

Germ cell tumors among infants and preschool children are rare. The most common tumor of pineal origin at this age is pineoblastoma or atypical teratoid/rhabdoid tumor. These tumors require histologic confirmation, and tumor resection is advised before adjuvant therapy.

39.9.2 Tumors of the Quadrigeminal Plate or Thalamic Origin

Hydrocephalus, if present, is treated with ETV. If the lesion is small and intrinsic, it can be followed closely with MR imaging. When tumor progression is confirmed, surgical resection may be advised. However, if the lesion is large, contrast-enhancing, or largely cystic, a craniotomy is indicated, and histologic diagnosis needs to be confirmed. For benign astrocytomas, once adequate tumor resection is accomplished, further follow-up is recommended. However, unresectable, progressive astrocytoma is treated with chemotherapy and/or RT.

Pearls

In this author's experience:

1. The histologic nature of a pineal region tumor of childhood is often predictable based on the sex, age, neuroimaging appearance, and tumor markers. However, if there is any doubt, one should confirm histology by means of ventriculotomy, stereotactic biopsy, or open craniotomy.
2. Hydrocephalus is the primary cause of symptoms. It is treated by endoscopic third ventriculostomy, when the CSF studies such as cytology and tumor markers are done.
3. Germinomas and most NGGCTs are chemosensitive. Neoadjuvant chemotherapy should be incorporated in the treatment protocol.
4. Pineal region tumors can be removed with minimum morbidity through supratentorial or posterior fossa approaches. Surgeons should be familiar with advantages and disadvantages of both approaches.

40 Medulloblastomas

Vijay Ramaswamy and Michael Taylor

Medulloblastomas are embryonal tumors arising from the cerebellum, initially described by Bailey and Cushing in 1925. Medulloblastoma is the most common malignant brain tumor of childhood, occurring at an incidence of 0.73 per 100,000 person-years and comprising approximately 25% of all pediatric brain tumors.¹ Medulloblastoma can occur in all age groups; however, it is most common in children younger than 9 years of age, and the incidence decreases with increasing age thereafter. There exists a modest male preponderance in a ratio of 1.4:1, which is most notable in children younger than age 4. In the past, medulloblastoma was classified as a primitive neuroectodermal tumor (PNET); however, recent data have shown that medulloblastoma is biologically distinct from other intracranial PNETs, specifically supratentorial PNETs, pineoblastoma, and brainstem PNETs. As such, medulloblastoma is considered a disease distinct from other intracranial PNETs. Recent advances over the past 20 years have significantly improved our understanding of the biology of medulloblastoma, and advances in chemotherapy and radiation therapy have significantly improved outcomes.

40.1 Clinical Presentation

The clinical signs and symptoms of medulloblastoma are usually related to hydrocephalus secondary to obstruction of the fourth ventricle. Most tumors are diagnosed when they are quite large and obstruct the flow of cerebrospinal fluid (CSF) in the fourth ventricle; before this, most either are asymptomatic or cause subtle clinical symptoms. Almost all children with medulloblastoma present with symptoms of increased intracranial pressure, specifically early morning vomiting and headache. The common sequence of events is early morning headache relieved by vomiting and resolution of symptoms. As the tumor progresses, the diurnal variation of the headache and vomiting tends to become less pronounced, and these symptoms are more constant. Truncal ataxia and diplopia secondary to sixth nerve palsy are also common presenting features in addition to vomiting and headache.² More lateral lesions may present with appendicular ataxia and occasionally focal weakness. Other neurologic symptoms localizing to the posterior fossa and brainstem can be present at diagnosis; however, they are much less common. Seizures rarely occur in children with medulloblastoma, and it is much more common for decerebrate posturing to be misinterpreted as tonic seizure. The time to diagnosis varies; however, children typically present acutely, and only rarely do children have a prediagnostic interval of longer than 2 months. It is not uncommon for children to undergo a gastrointestinal work-up before diagnosis. However, longer times to diagnosis do not correlate with reduced survival or worse neurologic outcome.³ The differential diagnosis for medulloblastoma at presentation includes ependymoma, pilocytic astrocytoma, atypical teratoid/rhabdoid tumor (AT/RT), and embryonal tumor with abundant neuropil and true rosettes (ETANTR). It can be difficult to distinguish these entities based on clinical symptoms alone, although children with pilocytic astrocytomas tend to have a longer duration of symptoms, and children with

ependymomas have a history of neck pain or stiffness with associated torticollis due to caudal invasion of the tumor through the foramen magnum.

Infants and very young children tend to have slightly different clinical presentations. Owing to their open sutures, infants present with macrocephaly and a head circumference that crosses percentiles. Infants with open sutures may present with irritability, lethargy, bulging fontanel, downward gaze due to pressure on the pretectum, and developmental arrest or regression. Very young children also tend to present with more catastrophic symptoms of hydrocephalus, such as apnea, bradycardia, and loss of consciousness, because of a more advanced stage of disease at diagnosis secondary to an increased tolerance of hydrocephalus. Adults commonly present with atypical symptoms and a longer prediagnostic interval because of a higher incidence of desmoplastic disease, which can arise in more lateral regions of the cerebellum. For example, patients who have cerebellopontine angle lesions present with vertigo, vomiting, nystagmus, and diplopia, which can be mistaken for vestibular canal symptomatology.

Metastatic disease is present in 40% of patients at diagnosis and is commonly asymptomatic; however, metastases may present with symptoms of nerve root involvement or spinal cord symptoms. Recurrent disease is rarely diagnosed clinically; rather, it is diagnosed on routine serial neuroimaging, and the likelihood of recurrence decreases with time.

Medulloblastoma can be associated with several familial cancer syndromes, specifically Gorlin syndrome, Turcot syndrome and Li-Fraumeni syndrome.⁴ Gorlin syndrome, also known as nevoid basal cell carcinoma syndrome, is present in 1 to 2% of patients with medulloblastoma and is an autosomal-dominant disorder associated with germline mutations in the *PTCH* gene on 9q31. The major criteria are multiple (more than two) basal cell carcinomas, jaw cysts (keratocysts) or bone cysts, palmar or plantar pits (more than three), early calcification of the falx cerebri, and a first-degree relative with Gorlin syndrome. Minor criteria include congenital skeletal abnormalities: specifically, rib abnormalities or fused vertebrae, macrocephaly, cardiac or ovarian fibroma, medulloblastoma, lymphomesenteric cysts, and various congenital malformations. Medulloblastoma in Gorlin syndrome usually develops before 2 years of age and is usually of desmoplastic histology and of the sonic hedgehog (SHH) subgroup. The outcome in these patients is more favorable than in those with sporadic medulloblastoma; however, basal cell carcinoma frequently develops in the irradiated skin, and these patients should be monitored on a long-term basis. Another germline mutation in the SHH pathway is *hSUFU*, which also leads to desmoplastic medulloblastoma but does not have the other manifestations seen in Gorlin syndrome.^{5,6} Turcot syndrome comprises distinct disorders: multiple colorectal neoplasms and tumors of the central nervous system (astrocytoma, medulloblastoma, pineoblastoma, ganglioglioma, ependymoma, glioblastoma). Medulloblastoma in patients with Turcot syndrome typically occurs before the age of 10 years and is not clinically different from sporadic disease. Turcot syndrome in medulloblastoma is associated with germline mutations in the adenomatous polyposis coli gene (*APC*) on 5q21. Li-Fraumeni syndrome is an autosomal-dominant disorder secondary to

germline missense mutations in the *TP53* gene on 17p13. Li-Fraumeni syndrome can lead to multiple different tumors, of which breast cancer, osteosarcoma, and brain tumors are the most common. Medulloblastoma occurs in approximately 5% of patients with Li-Fraumeni syndrome. Any patient with medulloblastoma and a strong family history of brain tumors or a previous history of an extraneural tumor warrants investigation for a germline *TP53* mutation and should be monitored on a lifelong basis for the development of other tumors. More rare familial syndromes associated with medulloblastoma include Bloom syndrome and Fanconi anemia. Bloom syndrome is an autosomal-recessive disorder characterized by dwarfism, sun sensitivity, and a characteristic facial appearance. It is more common in Ashkenazi Jews and is secondary to a mutation in the *BLM1* gene (RecQ protein-like-3) on 15q26.1. Fanconi anemia is an autosomal-recessive disorder that predisposes to bone marrow failure and leukemia and is secondary to several Fanconi anemia susceptibility genes.

40.2 Diagnostic Work-up

The initial diagnosis of medulloblastoma is usually made with noncontrast computed tomography (CT) followed by magnetic resonance (MR) imaging. On a noncontrast CT scan, a medullo-

blastoma is typically a hyperattenuating midline mass surrounded by vasogenic edema; it enhances homogeneously following the administration of contrast (► Fig. 40.1).⁷ The majority of lateral cerebellar medulloblastomas are of desmoplastic histology (► Fig. 40.2). Hydrocephalus is present on initial CT in over 95% of patients. The findings on CT are not specific for medulloblastoma and cannot reliably be distinguished from those of ependymoma or AT/RT. MR imaging with gadolinium enhancement is the preferred method for the initial evaluation of posterior fossa tumors. Younger children require general anesthesia for image acquisition, and care should be taken in these instances because there is a risk for respiratory depression. When sedation is indicated, it should be administered by a pediatric anesthesiologist. On T1-weighted MR imaging, medulloblastomas are hypointense or isointense relative to gray matter and become hyperintense with the administration of gadolinium. On T2-weighted imaging, the signal is variable and can be hyperintense to hypointense relative to gray matter. Diffusion-weighted imaging can be very useful in discriminating medulloblastoma from ependymoma or astrocytoma (► Fig. 40.3). Because medulloblastomas consist of dense small round cells with minimal cytoplasm and reduced free water, they exhibit diffusion restriction with a reduced apparent diffusion coefficient.

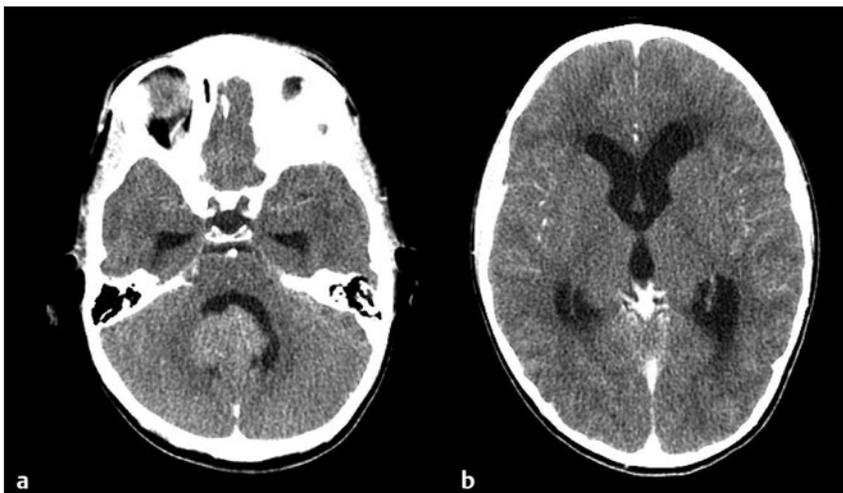

Fig. 40.1 Contrast-enhanced computed tomographic scan through the (a) posterior fossa and (b) third ventricle. Note the significant triventricular hydrocephalus at diagnosis.

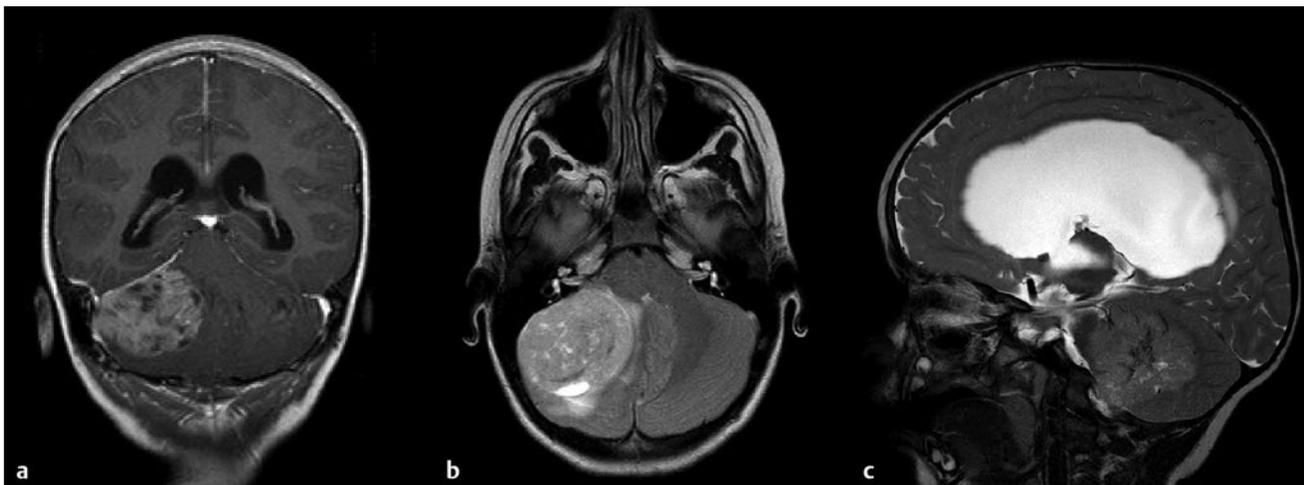

Fig. 40.2 (a) Coronal T1-weighted gadolinium-enhanced MRI. (b) Axial T2-weighted MRI. (c) Sagittal T2-weighted MRI showing a lateral desmoplastic tumor, commonly seen with the sonic hedgehog subgroup.

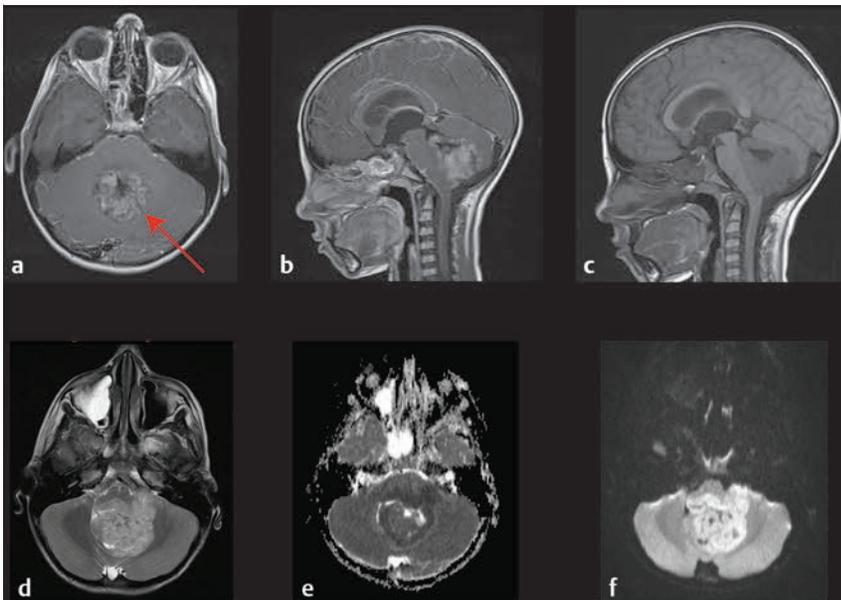

Fig. 40.3 Magnetic resonance (MR) image at diagnosis of a midline medulloblastoma. (a) Axial and (b) sagittal T1-weighted gadolinium-enhanced MR images. Note the homogeneous enhancement following contrast administration. (c) Sagittal T1-weighted unenhanced MR image. (d) Axial T2-weighted MR image (note the peritumoral edema). (e) Axial apparent diffusion coefficient (ADC) map and (f) axial diffusion-weighted Image (b1000). Note the restricted diffusion observed throughout the tumor.

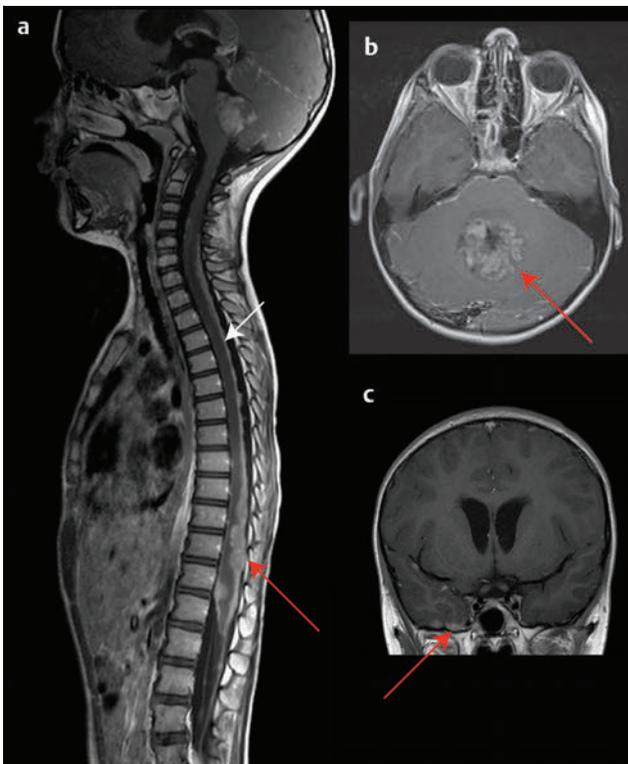

Fig. 40.4 Metastatic medulloblastoma. (a) Sagittal T1-weighted gadolinium-enhanced magnetic resonance (MR) image of the entire spinal cord showing diffuse nodular (red arrow) leptomeningeal metastases throughout the entire spine. (b) Sagittal T1-weighted gadolinium-enhanced MR image of the lower thoracic and lumbar spinal cord showing a classic "sugar coating" pattern of laminar metastases (white arrow) covering the spinal leptomeninges. (c) Coronal T1-weighted gadolinium-enhanced MR image showing supratentorial nodular metastases (red arrow) along the inferior surface of the right temporal lobe.

This is in contrast to ependymomas and pilocytic astrocytomas, which typically do not have restricted diffusion.⁸ AT/RTs also display restricted diffusion; however, young age of the patient, cerebellopontine angle involvement, and intratumoral hemorrhage can help distinguish AT/RTs from medulloblastomas radiologically.⁹ When feasible, preoperative imaging of the entire craniospinal axis is desirable for adequate staging of disease because 40% of medulloblastomas are metastatic at diagnosis (► Fig. 40.4). However, imaging of the entire craniospinal axis should be performed 2 weeks or later postoperatively for full staging to avoid the possibility of false-positives due to debris and blood products.¹⁰ Cranial MR imaging should also be repeated within 72 hours postoperatively or after 2 weeks postoperatively because residual tumor of more than 1.5 cm² may be correlated with a higher risk for disease.¹¹ Cranial MR imaging performed between 3 and 14 days postoperatively can be falsely positive because of the presence of blood products and debris. Ultimately, pathologic diagnosis is required for a firm diagnosis.

Lumbar CSF sampling is also warranted in every patient with a new diagnosis of medulloblastoma. Lumbar sampling is preferred over ventricular sampling at surgery or through a shunt because lumbar CSF sampling is more sensitive than ventricular sampling.^{12,13} Ideally, both ventricular CSF sampling at surgery and lumbar CSF sampling 2 weeks postoperatively should be obtained because there are cases of discordance between the two sites, and positive ventricular CSF cytology intraoperatively has been associated with a poorer outcome.^{13,14} Spinal MR imaging is not a substitute for lumbar CSF sampling and vice versa because up to 18% of cases of leptomeningeal disease can be missed if only one of the two modalities is used.¹⁵

There are a paucity of data regarding the role of bone marrow sampling at diagnosis; however, routine extraneural staging is not warranted because extra neural disease is extremely uncommon at diagnosis. If there is suspicion of extraneural disease, FDG-PET (fluorodeoxyglucose F 18 positron emission tomography) and bone marrow biopsy are the preferred modalities. Bone marrow sampling should be considered if the

child will be undergoing autologous stem cell harvest as part of the treatment regimen. Extraneural disease is more commonly present at recurrence, particularly very late recurrences, and can be present in the absence of intracranial disease.¹⁶ Hearing and creatinine clearance should be evaluated postoperatively in all patients before the initiation of either radiation therapy or chemotherapy because both platinum-based chemotherapy and radiotherapy are ototoxic and nephrotoxic.

40.3 Hydrocephalus

The majority of patients with medulloblastoma present with hydrocephalus due to obstruction of the fourth ventricle. As such, the management of hydrocephalus is usually the first intervention. Most patients can be managed with preoperative dexamethasone (0.45 mg/kg per day divided into three doses, with an initial dose of 0.45 mg/kg), which results in significant alleviation of the symptoms and a reduction in vomiting. Placement of an extraventricular drain (EVD) preoperatively is occasionally necessary; however, in instances in which hydrocephalus is resulting in cardiopulmonary instability and/or in cases of impending herniation, it is warranted as a tempering measure until resection can take place. When an EVD is placed, consideration must be given to the possibility of upward herniation, and the rate and quantity of CSF drainage must be carefully monitored. The height of an EVD can be gradually increased in the postoperative period, and in most cases the EVD can be successfully removed within a week to 10 days postoperatively. From 10 to 40% of children require permanent CSF diversion postoperatively, and as such, routine ventriculoperitoneal shunting is not indicated perioperatively. The need for shunting is greatest in young children and in those with very large ventricles at diagnosis, more extensive tumors, and metastatic disease.¹⁷ CSF diversion is rarely required in children older than age 10. When persistent hydrocephalus is present, either ventriculoperitoneal shunting or endoscopic third ventriculostomy can be considered.¹⁸ Several series have reported high success rates with endoscopic third ventriculostomy for persistent hydrocephalus, and it should be considered in patients requiring postoperative shunting who are suitable candidates for this procedure. There is limited evidence for the use of routine endoscopic third ventriculostomy in all patients because a significant proportion of patients do not have persistent hydrocephalus.¹⁸ Rare cases of peritoneal seeding of medulloblastoma through ventriculoperitoneal shunts have been described.¹⁹

40.4 Tumor Resection

Gross total resection of the primary posterior fossa mass through a suboccipital craniotomy is the most common initial treatment for medulloblastoma. The goal of surgical resection is to achieve a gross total resection or, if this is not possible, to resect as much of the tumor as is safely possible. There is seldom any role for a limited biopsy. The craniotomy is performed with the patient in the prone position and the neck flexed. Once the superficial tissues and muscles are dissected, a portion of the occipital bone and the lamina of C1 are removed. The dura covering the cerebellum is then opened, and the two hemispheres are retracted through either the split vermis or a telovelar

approach. Although medulloblastoma rarely invades the floor of the fourth ventricle, it is important to visualize the floor of the fourth ventricle at the onset of the surgery to ensure that the resection is not carried into the brainstem. Severe cranial nerve palsies can result if the surgeon aggressively resects tumor that invades the brainstem, and this is never indicated because the tumor is sensitive to both chemotherapy and radiation, and residual brainstem disease likely does not significantly alter outcome.¹¹ If the tumor invades the cerebellopontine angle, then the use of intraoperative brainstem auditory evoked potentials can be considered. Medulloblastomas can be fairly vascular, leading to considerable hemorrhage intraoperatively, and care should be taken to prevent blood loss, particularly in young children. Dural closure should be achieved in a watertight fashion and the bone replaced after the procedure has been performed. Postoperative MR imaging should be performed to determine the extent of resection within 72 hours of surgery so as to avoid obscuration by blood products and gliosis. Residual disease over 1.5 cm² is possibly associated with poorer outcome, and repeated resection for large residual tumor should be considered unless the surgeon stopped the initial resection because of excessive vascularity or invasion of critical structures.¹¹

40.5 Pathology

The definitive diagnosis of medulloblastoma is made on microscopic pathologic examination. On gross examination, medulloblastoma appears as a pinkish gray to purple mass with a clear interface separating it from normal cerebellum. In the operating room, it also appears as a highly vascular lesion owing to its blood supply principally from the posterior inferior cerebellar artery. Leptomeningeal metastases may be seen at the time of surgical resection as well, which appear as a whitish coating that resembles icing sugar. On microscopic examination, medulloblastoma appears as a “small round blue cell tumor” and is morphologically indistinguishable from supratentorial PNETs or pineoblastomas. Medulloblastomas are highly cellular and the cells are densely packed, with prominent nuclei and scant cytoplasm. A type of pseudorosette may be seen (Homer-Wright rosette) in which differentiated cells surround the neuropil. Histologically, there are three main types of medulloblastoma: (1) classic, (2) desmoplastic, and (3) large cell/anaplastic. Classic histology is by far the most common histology (>70%) and consists of sheets of small blue cells with densely packed isomorphic nuclei and a high proliferative index. Desmoplastic histology is more common in infants and adults and is most commonly associated with SHH pathway activation. Desmoplastic histology is characterized by nodules with a paucity of tumor cells surrounded by cells with a higher density, more pleomorphic nuclei, and densely packed reticulin fibers. Within the nodules, there is increased synaptophysin staining, and outside the nodules, there is a higher Ki-67 proliferation index, and the tumor cells are GFAP (glial fibrillary acidic protein)-positive. There is no consensus regarding how much desmoplasia is required to classify a tumor as desmoplastic. A variant of desmoplastic histology termed medulloblastoma with extensive nodularity (MBEN) is characterized by extensive nodularity and neuronal differentiation. The desmoplastic and MBEN variants in infants signified a favorable prognosis in several studies.²⁰ The large cell/anaplastic variant is aggressive and characterized

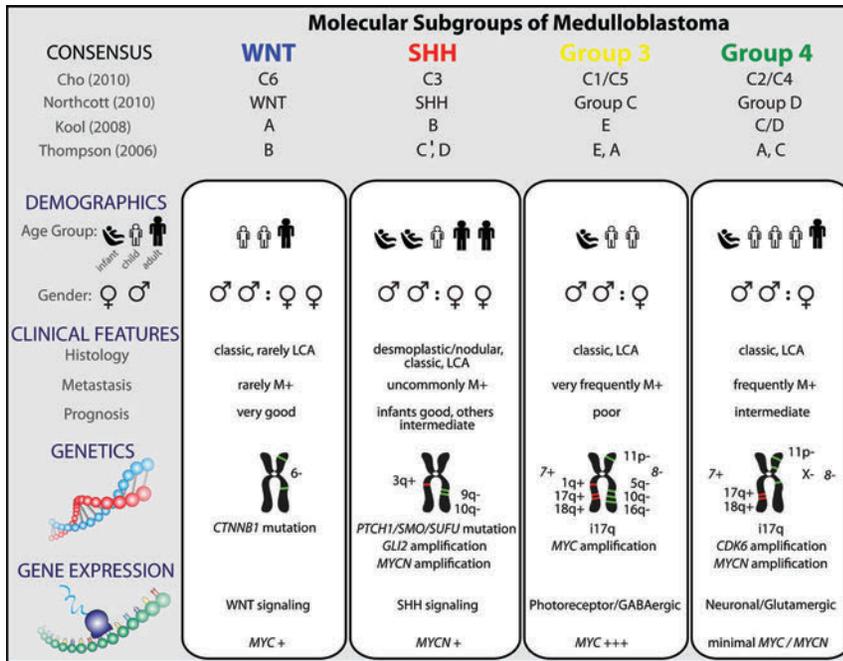

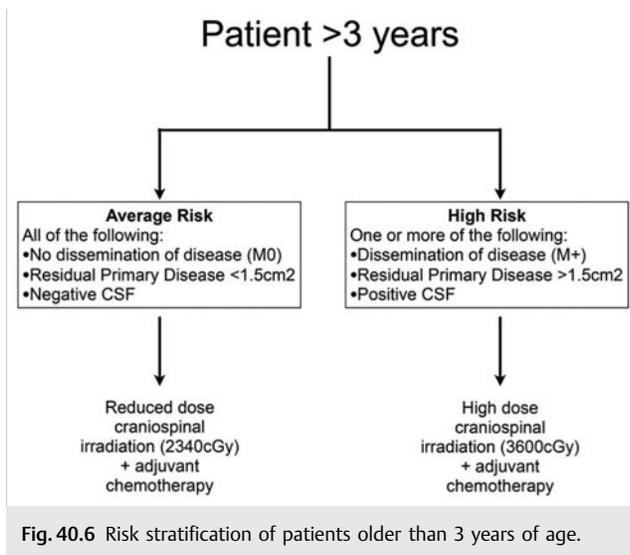

Fig. 40.5 Consensus molecular subgroups of medulloblastoma. Comparison of the various subgroups of medulloblastoma, including patient demographics, common genetic changes, and outcome. GABA, γ -aminobutyric acid; LCA, large cell/anaplastic; SHH, sonic hedgehog. (Used with permission from Taylor MD, Northcott PA, Korshunov A, et al. Molecular subgroups of medulloblastoma: the current consensus. *Acta Neuropathol* 2012;123:467.)

histologically by large, irregular, and pleomorphic nuclei; circumscribed foci of necrosis; and apoptotic bodies. The large cell variant tends to have prominent nucleoli. The large cell/anaplastic variant accounts for approximately 4%, is more common in the group 3 molecular subgroup, is commonly associated with bulky spinal metastases at diagnosis, and has a poor prognosis. Pathologic variants include the medulloblastoma, which is characterized by a striated muscle component, and the melanotic medulloblastoma, which is characterized by a pigmented epithelial component forming tubules or clusters. Medulloblastomas are more commonly associated with isochromosome 17q, have frequent *MYC* amplification, and tend to be of large cell/anaplastic histology; however, because of a paucity of multicenter studies, their prognosis is indeterminate.²¹ Melanotic medulloblastoma is very rare, and its prognostic significance is unclear.

The pathologic differential diagnosis for medulloblastoma includes AT/RTs and ETANTRs. AT/RTs are most common in young infants and should be considered in any child younger than age 5 with medulloblastoma, or when a rhabdoid component is present on histologic examination. Molecularly, AT/RTs are characterized by loss of *INI1/hSNF5*. Therefore, INI1 immunoreactivity should be assessed in all infants in whom medulloblastoma is diagnosed; in AT/RTs, staining for INI1 will be negative in the tumor but positive in blood vessels, and in medulloblastoma, staining will be positive in both tumor and blood vessels. ETANTRs are rare tumors that can occur in any location, including the posterior fossa, and were previously called ependymoblastomas. ETANTRs are characterized molecularly by focal amplification of a microRNA cluster at the 19q13.42 locus and should be considered when the pathologic features include ependymoblastic rosettes and neuronal differentiation on a neuropil background.²² ETANTRs are found in young infants and portend a poor prognosis.

The advent of integrated genomics over the past 20 years has significantly advanced our understanding of the biology of

medulloblastoma. Several integrated genomic studies during the past 6 years have revealed that medulloblastoma comprises at least four variants, which are transcriptionally, genetically, and clinically distinct.^{23–25} These four subgroups are termed WNT, sonic hedgehog (SHH), group 3, and group 4 (► Fig. 40.5). The four molecular subgroups have significant prognostic value and predict survival independently of the presence of metastases or unfavorable histology. The WNT subgroup is characterized by activation of the WNT pathway, and tumors commonly harbor mutations in the β -catenin gene (*CTNNB1*). Patients with WNT-activated tumors, which occur primarily outside the infant age group, tend to have a very favorable prognosis.^{24,26} Patients with WNT-activated tumors are being considered for de-escalation of therapy in future clinical trial designs. The SHH subgroup is characterized by activation of the SHH pathway and is more common in infants with desmoplastic tumors and in adults; however, it can occur in all age groups and is associated with all histological variants. Infants with desmoplastic SHH-activated tumors have a favorable prognosis; however, other SHH-activated tumors have an intermediate prognosis. SHH pathway inhibitors such as smoothened inhibitors are currently in clinical trials and hold promise for personalized therapy in this subgroup of patients.²⁷ Group 3 medulloblastomas have a poor prognosis and are commonly associated with metastatic disease. *MYC* amplification is common in group 3 medulloblastomas, and the survival rate in these patients is dismal. Group 4 medulloblastomas have an intermediate prognosis and are commonly associated with isochromosome 17q and *MYCN* amplification. A molecular subgroup can be determined through several methods, including immunohistochemistry with a four-antibody method (DKK1 for WNT, SFRP1 for SHH, NPR3 for group 3, and KCNA1 for group 4) and gene expression profiling through either a whole transcriptome or a limited-gene approach.^{23,28} WNT subgroup medulloblastomas can also be diagnosed through nuclear immunoreactivity of β -catenin.²⁹ Other immunohistochemical approaches for the diagnosis of the four

subgroups include GAB1 immunoreactivity for SHH and negativity for YAP1 and filamin A for non-SHH/WNT. Markers of a poor prognosis for non-SHH/WNT subgroups include *FSTL5* overexpression, *MYC* amplification, *MYCN* amplification, and gain of chromosome 17q.^{24,30} *TP53* mutations have been suggested to portend a poor prognosis; however, the literature surrounding this is conflicting, including the observation that patients with *TP53* mutations in WNT-activated tumors have a good survival.^{31,32}

40.6 Staging and Outcome

The Chang system is the most commonly used staging system (see box “Chang Staging of Medulloblastoma (p.532)”). Children older than age 3 are categorized as having average-risk or high-risk disease based on the Chang staging system (► Fig. 40.6). The prognosis of patients with metastases does not differ for M1, M2, and M3.³³ A T-staging system of tumor invasiveness also exists; however, it is unclear whether this holds any prognostic value. All patients older than the age of 3 years with no evidence of disseminated disease and residual tumor at the primary site of less than 1.5 cm² are classified as having average-risk medulloblastoma. All patients younger than age 3 are designated as high-risk. Patients older than age 3 with average-risk disease have a 5-year survival rate of 85% with combined chemotherapy and reduced-dose radiotherapy, and patients older than age 3 with high-risk disease have a 5-year survival rate of 70% with combined chemotherapy and high-dose radiation therapy.^{26,34} In children younger than 3, histology is predictive of outcome; specifically, children with desmoplastic histology have a 2-year overall survival rate of 85%, compared with 34% for patients with other histologies.²⁰

Chang Staging of Medulloblastoma

- M stage
 - No evidence of tumor dissemination, with CSF negative for tumor cells
 - CSF positive for tumor cells

- Dissemination of disease into intracranial leptomeninges or lateral/third ventricle
- Dissemination of disease into intraspinal leptomeninges
- Dissemination of disease outside the central nervous system
- T stage
 - Tumor < 3 cm in diameter
 - Tumor > 3 cm in diameter
 - Tumor > 3 cm with spread to nearby structures
 - Tumor > 3 cm with spread into the brainstem
 - Tumor > 3 cm with rostral extension past the aqueduct of Sylvius or caudal extension past the foramen magnum

40.7 Nonsurgical Treatment

40.7.1 Radiation Therapy

Patients older than 3 years of age with average-risk disease are treated with reduced-dose (2,340 cGy) craniospinal irradiation, with a boost to the tumor bed or posterior fossa of 5,400 to 5,580 Gy after surgical resection of the primary tumor.^{26,34} Radiation therapy is followed by adjuvant, cisplatin-based chemotherapy in patients with average-risk disease and results in survivals of approximately 85% across several regimens.^{26,34} Radiation therapy is often given concomitantly with chemotherapy, typically vincristine. Patients who have high-risk disease are treated with 3,600 cGy of craniospinal irradiation, with a boost to the tumor bed and to focal metastases followed by adjuvant chemotherapy, resulting in survival of approximately 70%.²⁶ A delay of radiotherapy past 28 days postoperatively has a negative prognostic impact.³⁵ Chemotherapy with standard regimens before radiation has been investigated and results in inferior survival.³⁶ The role of hypofractionated radiotherapy is unclear; however, its use following chemotherapy can lead to good outcomes in high-risk disease.³⁷ Radiation therapy is associated with several adverse effects, particularly cognitive impairment, in younger children. Ototoxicity, thyroid dysfunction, growth failure, and radiation necrosis are frequently observed side effects of radiation therapy and are inversely correlated with age.^{38,39} The role of repeated irradiation for recurrent disease is unclear; however, a few studies have shown a benefit, specifically in focal recurrences, when repeated irradiation is combined with repeated resection.⁴⁰ Moreover, salvage radiotherapy for recurrent disease in infants treated with chemotherapy alone can significantly improve survival, particularly in those with local relapse.^{20,41,42} Children younger than age 3 have devastating cognitive outcomes when receiving craniospinal irradiation, and as such, protocols using chemotherapy alone are preferred despite inferior outcomes.³⁸

40.7.2 Chemotherapy

Current therapy for all patients with medulloblastoma includes chemotherapy. Children younger than age 3 are treated with chemotherapy-only approaches, even in cases of disseminated disease. Three approaches have been studied for infant medulloblastoma, including systemic induction chemotherapy, followed by myeloablative chemotherapy with autologous stem cell support, followed by radiotherapy for local relapse (Children’s Oncology Group [COG], Headstart, Société Française d’Oncologie Pédiatrique [SFOP]), combined systemic and intraventricular

chemotherapy (German Society for Pediatric Oncology and Hematology [GPOH]), and systemic chemotherapy with conformal local radiotherapy (United Kingdom, Children's Oncology Group).⁴² All three of these approaches result in similar 5-year overall survival rates of approximately 50 to 70%, with the desmoplastic variant having survivals close to 90%.⁴² The intraventricular methotrexate approach requires placement of an Ommaya catheter or a programmable shunt and adequate CSF flow. Intraventricular methotrexate should not be administered through a ventriculoperitoneal shunt without a device for transient occlusion to prevent methotrexate-induced peritonitis. Furthermore, intraventricular methotrexate is associated with a dose-dependent leukoencephalopathy of varying severity, and patients are at risk for radiation necrosis if they subsequently require radiation therapy. Young children treated with intrathecal methotrexate have a high risk for developing significant cognitive deficits, particularly in measures of intelligence and memory.⁴³ Patients older than age 3 with average-risk disease are treated with four to nine cycles of combination postirradiation adjuvant chemotherapy, which is usually cisplatin-based. Patients with high-risk disease have been treated with a variety of approaches; however, all these approaches administer adjuvant chemotherapy following high-dose craniospinal irradiation, with 5-year overall survival rates of approximately 70%.²⁶

Chemotherapeutic options for recurrent disease, particularly in children with prior irradiation, are limited. One potential option for recurrent disease is the use of high-dose chemotherapy with autologous stem cell support with or without repeated irradiation, which can result in long-term survival in 10 to 25% of patients.⁴⁴ However, these studies also suggest that the outcome is favorable only in those patients with no evidence of disease or minimal residual disease at the time of high-dose chemotherapy. Several agents are active against recurrent disease; however, there are very few long-term survivors, and the enrollment of patients with recurrent disease into a clinical trial is a reasonable option.

40.8 Complication: Posterior Fossa Syndrome

The most common postoperative complication is the posterior fossa syndrome, also referred to as cerebellar mutism or cerebellar affective syndrome. In a prospective Children's Cancer Group questionnaire-based study, approximately 22% of patients developed posterior fossa syndrome postoperatively; however, these cases were rated as moderate to severe, suggesting that the incidence of milder cases may be much higher.⁴⁵ The symptoms typically manifest 24 to 48 hours postoperatively.⁴⁶ Posterior fossa syndrome is characterized by a triad of (1) decreased production of speech or mutism, (2) cerebellar dysfunction including ataxia and axial hypotonia, and (3) neurobehavioral affective symptoms such as emotional lability, irritability, and apathy.^{47,48} The neurobehavioral symptoms can be the most distressing to families because children typically are inconsolable with sharp, high-pitched whining and display marked apathy with a lack of initiation and hypokinesia. Other symptoms, such as decreased oral intake and oromotor apraxia, have also been described with the syndrome.⁴⁸ Fecal and urinary incontinence has been observed in up to 60% of patients.⁴⁷ The pathophysiol-

ogy of posterior fossa syndrome is not completely known; however, there is evidence that perturbations in the proximal dento-thalamocortical pathway as a result of the midline tumor and/or surgical resection are causative.⁴⁹ Furthermore, there is increasing evidence pointing to the role of the cerebellum in speech initiation. Some studies have attempted to correlate tumor size with the development of posterior fossa syndrome; however, results of these studies have been inconclusive. There is also recent evidence of presurgical language impairment as a primary risk factor for development of the posterior fossa syndrome; children without a presurgical language deficit did not develop mutism, suggesting that the technical aspects of surgery are unlikely to be causative.⁵⁰ To this effect, surgical approaches that avoid splitting the cerebellar vermis do not seem to prevent development of the posterior fossa syndrome.^{47,48} The outcome of posterior fossa syndrome is variable. Typically, the child recovers from mutism at a mean of 8.3 weeks; however, a residual ataxic dysarthria is common. Indeed, speech impairments were present in 95% of patients with moderate or severe mutism 1 year postoperatively.⁴⁵ Other neuropsychiatric deficits are also noted in patients with posterior fossa syndrome, such as deficits in receptive language, memory impairment, cognitive function, and executive function, suggesting that multidisciplinary rehabilitation is required in these patients.^{45,48} There are no available modalities for either the treatment or prevention of posterior fossa syndrome that have been shown to be effective beyond the level of anecdotal reports. An intensive multidisciplinary rehabilitation program involving neurologists, physiatrists, and oncologists as well as speech, occupational, and physical therapists is required to manage the global neurologic dysfunction observed in these patients.

Pearls

- Pathologic diagnosis is necessary for all cases of medulloblastoma. Frozen tissue should be banked in all patients for molecular studies.
- Aggressive resection of brainstem infiltration is neither desired nor warranted; residual brainstem disease can be treated with radiation and/or chemotherapy and does not hold any negative prognostic value.
- A complete tumor staging work-up should be performed in every patient, including postoperative MR imaging of the entire neuroaxis and a lumbar CSF examination 2 weeks postoperatively.
- Radiation therapy in children older than age 3 should be initiated before 28 days postoperatively.
- Most children do not require postoperative ventriculoperitoneal shunting and can be successfully weaned from an extraventricular drain. Endoscopic third ventriculostomy should be considered in suitable candidates when CSF diversion is required.

41 Ependymomas

Scott D. Wait, Michael Taylor, and Frederick A. Boop

Ependymoma is the third most common pediatric brain tumor, following medulloblastoma and astrocytoma in incidence. Pediatric neurosurgeons play an important role in treatment because ependymoma with gross total resection (GTR) have a high likelihood of cure, whereas those who do not fare poorly. Current standard therapy consists of GTR if possible, followed by local radiotherapy. Chemotherapy plays a less well-defined role in a minority of patients. Although many children with ependymoma are cured, a minority of children still die of this disease, illustrating the need for further clinical and basic science research on ependymomas.

41.1 Epidemiology, Clinical Presentation, and Pathogenesis

Neurosurgeons often speak of ependymomas as a homogeneous group of tumors despite several histologic variants, each with a distinct biology. Even among those tumors that are diagnosed as classic ependymomas on histopathology, there are several different types, again each with its own biology.^{1,2} Most current clinical and basic science studies deal with the ependymomas as a group, even though they diverge in regard to epidemiology, natural history, pathophysiology, and response to treatment.

The mean age at the diagnosis of pediatric ependymoma is 4 to 6 years, with about one-third of tumors diagnosed before the age of 3 years.³⁻⁷ Approximately 10% of pediatric brain tumors belong to the ependymoma group of tumors, comprising a much higher percentage than in the brain tumors of adults. Historical 5-year survival estimates range from 50 to 64%, with the progression-free survival (PFS) estimated rate lower, at 23 to 45%.^{6,8-11} In most cases, recurrence is found at the site of the original tumor, with isolated metastatic recurrence occurring in fewer than 20% of cases. Most children who have no evidence of disease at 5 years will be cured. The median time to recurrence is 13 to 25 months.^{32,69,74,76,83} Strikingly different from patients with medulloblastoma, those with ependymomas present with evidence of leptomeningeal dissemination at the time of diagnosis in only 5% of cases.⁶ The diagnosis of leptomeningeal metastases is made by contrast magnetic resonance (MR) imaging and/or cytologic examination of the cerebrospinal fluid (CSF). The results of both must be negative for a child to be ruled without metastatic disease. In children with ependymoma and a ventriculoperitoneal (VP) shunt, CSF obtained by lumbar puncture is more sensitive in detecting leptomeningeal disease.¹²

Relatively little is known of the pathogenesis of ependymomas compared with other childhood brain tumors. Ependymomas are thought to arise from radial glial cell precursors.¹³ In childhood, 90% of ependymomas are located intracranially, one-third supratentorially, and two-thirds infratentorially (► Fig. 41.1).¹⁴ Sixty percent of supratentorial ependymomas are in or adjacent to the ventricles, whereas the other 40% arise away from ependymal surfaces (► Fig. 41.2).

Infratentorial (posterior fossa) ependymomas are thought to arise from three different sites in the fourth ventricle: the floor (60%), the lateral aspect (30%), and the roof (10%).^{15,16} Tumors that arise from the floor often extend out through the foramen of Magendie over the dorsal aspect of the spinal cord. Tumors arising more laterally may extend out of the foramen of Luschka to involve the contents of the cerebellopontine angle (CPA).

41.2 Outcome and Prognostic Factors

Many authors have examined prognostic factors in ependymoma. The most important prognostic factor is extent of resection. Other clinical variables thought to be prognostic include extent of disease at diagnosis (M status), tumor location, tumor grade, and patient age at diagnosis. There is no formally recognized staging system for ependymomas, although the importance of leptomeningeal dissemination is well known. Children are staged at the time of diagnosis or shortly after surgery with cranial and spinal MR imaging as well as examination of cerebrospinal fluid (CSF) cytology. Long-term survival is uncommon in children with M+ disease.

41.2.1 Extent of Resection

The single most important determinant of outcome in cases of pediatric ependymoma is the extent of surgical resection. The pediatric neurosurgeon must achieve a maximal safe resection. The 5-year survival rate in children who receive a GTR is 67 to 80%, and the 5-year PFS rate is 51 to 75%.^{4-7,9-11,17-25} In striking comparison, the 5-year survival rate of children who undergo subtotal resection is 22 to 47%, and 5-year PFS rate is 0 to 26%. Thus, many authors suggest that pediatric patients with ependymoma and residual tumor on postoperative imaging undergo a repeated resection.^{16,19,26,27}

Many neurosurgeons classify ependymoma resections as gross total resection (GTR), near-total resection (NTR), subtotal resection (STR), and biopsy. The extent of surgical resection should be confirmed by postoperative MR imaging with and without gadolinium within 72 hours of resection to avoid confusing postoperative artifacts. A GTR is defined as absence of tumor on postoperative MR imaging. If a thin carpet of tumor is left on the floor of the fourth ventricle (and is visualized with the operating microscope at the time of surgery), but there is no evidence of tumor on postoperative MR imaging, this still qualifies as a GTR at St. Jude Children's Research Hospital (Memphis, Tennessee). A resection is subtotal when gross residual tumor (more than a fourth ventricular layer) remains after surgery that was visible to the surgeon or evident on neuroimaging. Although NTR was once thought to be prognostically similar to GTR and has been arbitrarily defined as less than 1.5 cm³ on postoperative imaging (similar to the values quoted for medulloblastoma) and/or a 0.5-cm residual thickness of tumor bed enhancement, longer follow-up has shown that these patients actually stratify more closely to

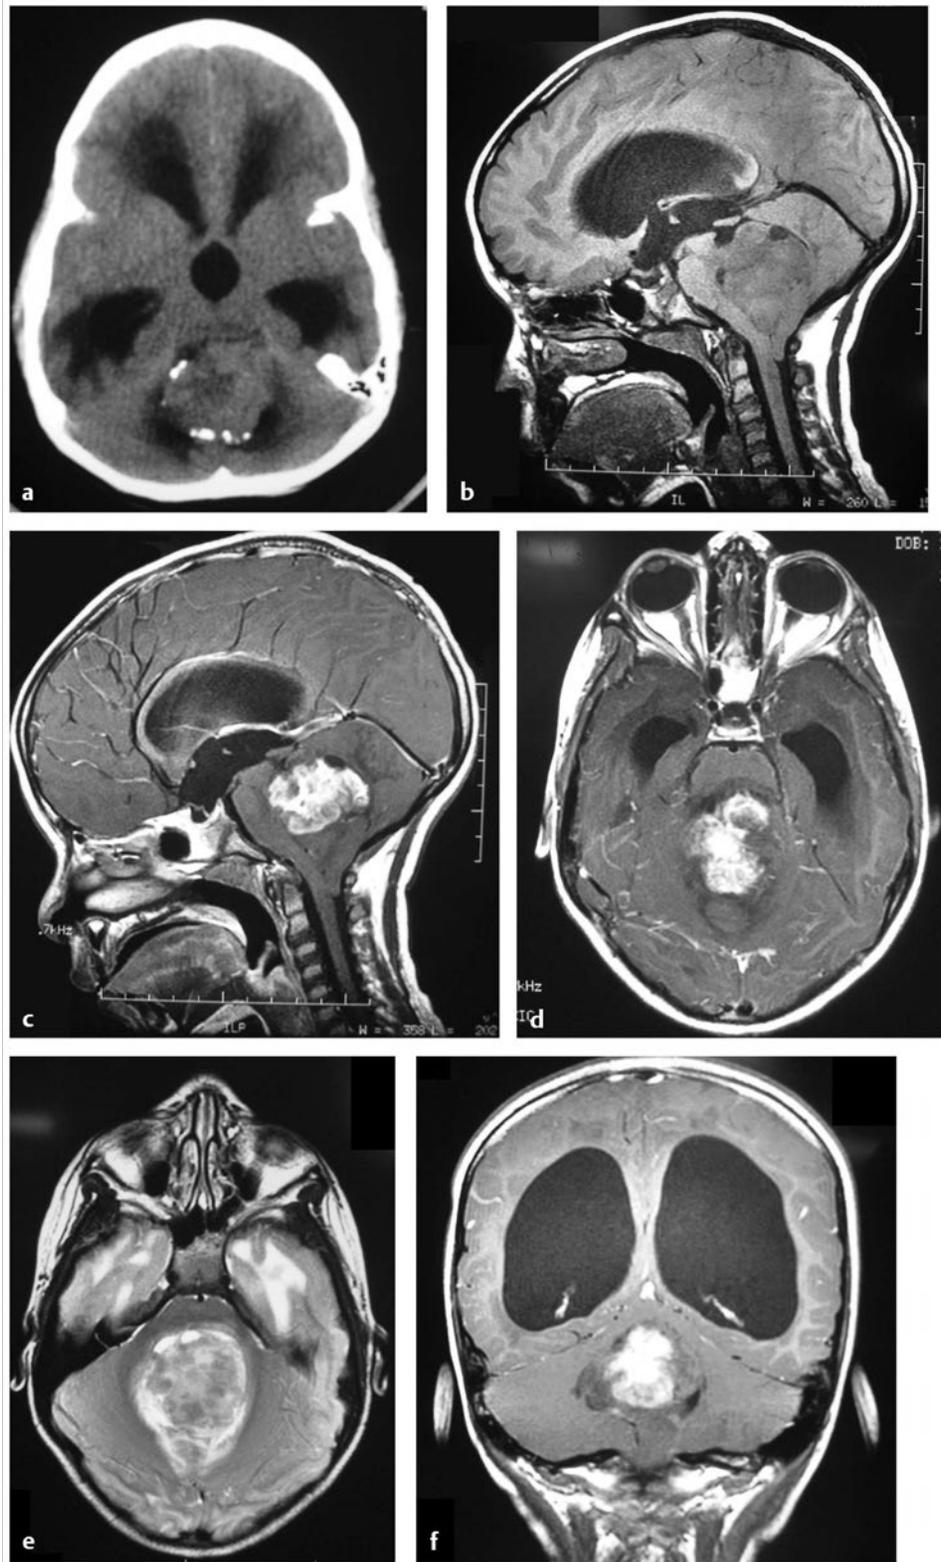

Fig. 41.1 A 5-year-old with headaches and vomiting. (a) An unenhanced computed tomography (CT) scan shows a posterior fossa tumor, with some peripheral calcifications. There is associated supratentorial noncommunicating hydrocephalus from obstruction of the fourth ventricle. (b) Sagittal T1-weighted magnetic resonance (MR) image without intravenous contrast shows a mass lesion in the fourth ventricle that is isointense or hypointense to the brain. Note that the tumor and the cerebellum have protruded down through the foramen magnum. (c) Sagittal T1-weighted MR image with intravenous contrast shows enhancement of the superior portion of the tumor. One of the critical pitfalls in ependymoma surgery is failure to recognize the nonenhancing portion of the tumor. (d) Axial T1-weighted MR image with contrast. (e) Axial T2-weighted MR image shows a high-signal mass lesion in the fourth ventricle. (f) Coronal T1-weighted MR image with contrast shows supratentorial hydrocephalus and the partially enhancing, partially nonenhancing tumor. The nonenhancing portion of the tumor is extending out through the foramen of Magendie.

patients with STR, making us even more aggressive about a return to surgery for small amounts of residual tumor; however, we do not return to surgery for a layer of tumor invading the floor of the fourth ventricle unless it is bulky disease.^{11,19} Recent studies, based upon molecular profiling of ependymomas, suggest that fourth ventricular ependymomas

that invade the floor of the fourth ventricle have a better prognosis than do lateral ependymomas, regardless of the extent of resection.² This is a very important concept for the pediatric neurosurgeon; it is not necessary to perform extensive, overly aggressive resections in this location (i.e., chase an ependymoma into the floor of the fourth ventricle)

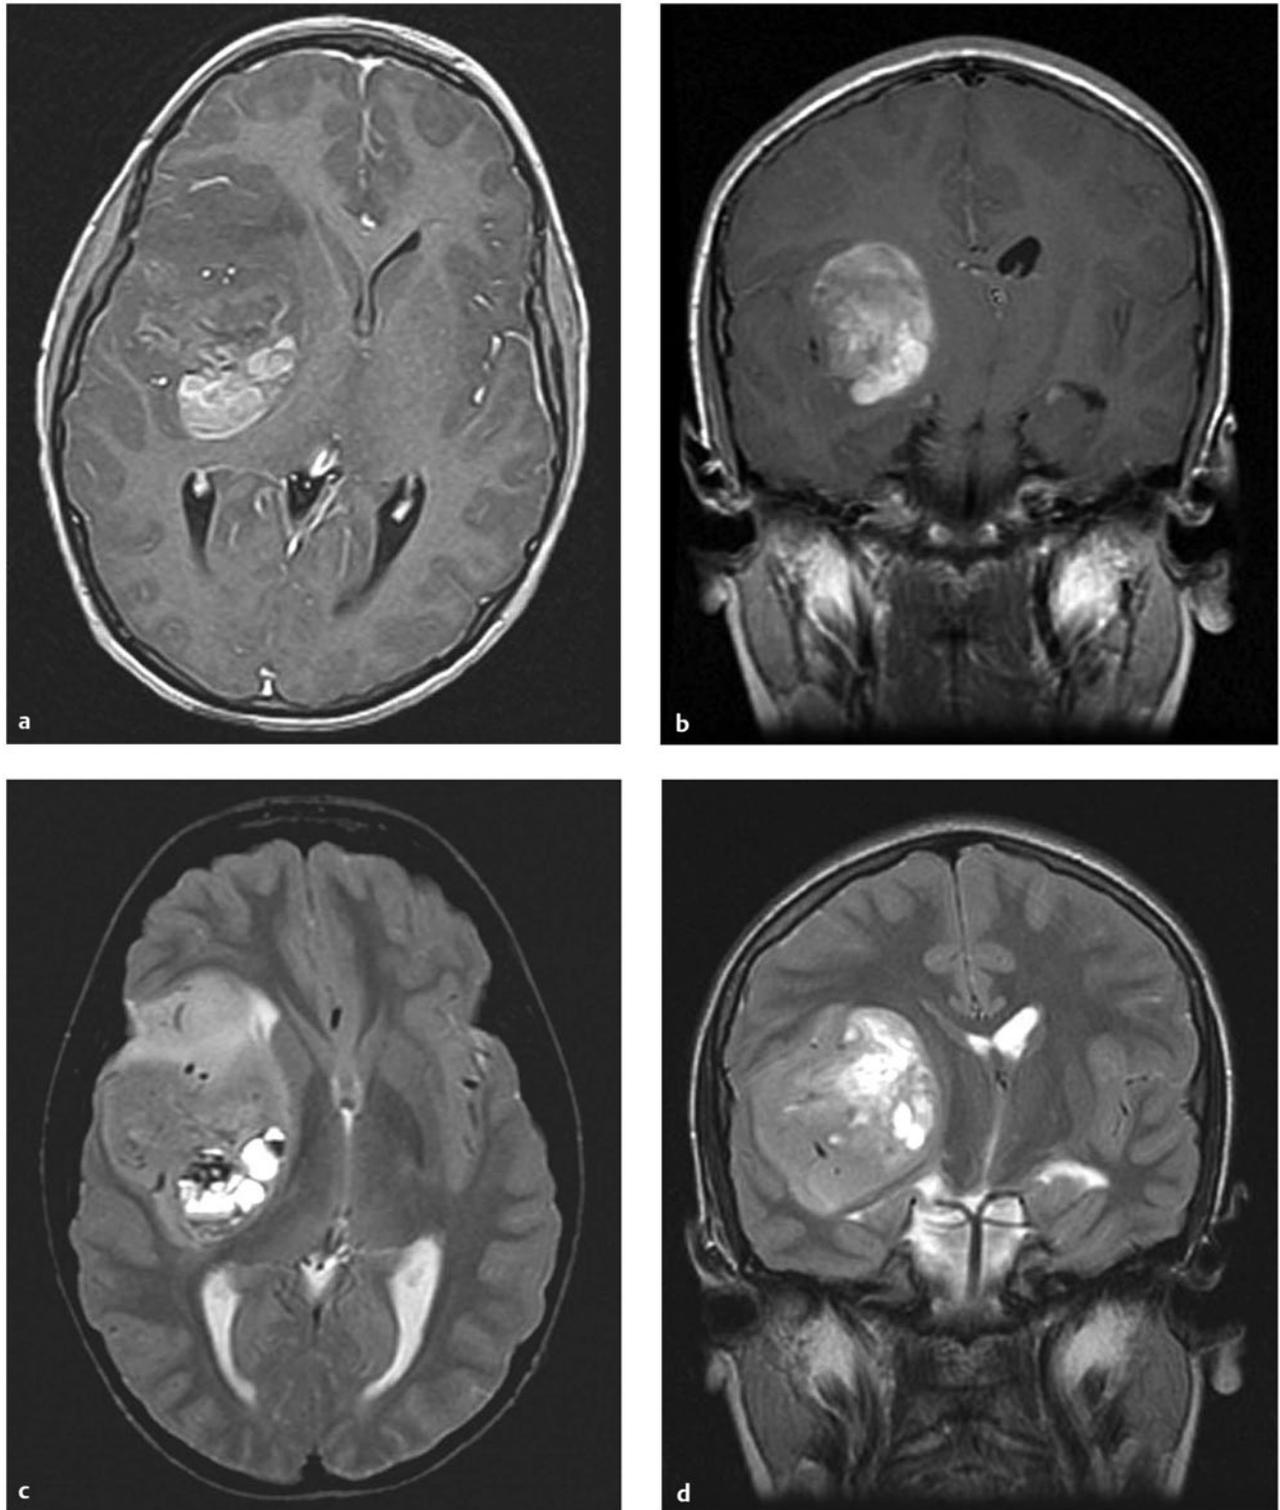

Fig. 41.2 Supratentorial ependymoma. (a) Axial T1-weighted magnetic resonance (MR) image with gadolinium shows a hemispheric mass lesion, partially enhancing, partially nonenhancing, in the right frontal operculum. (b) Coronal T1-weighted MR image with gadolinium. (c) Axial T2-weighted MR image. Note the paucity of peritumoral edema. (d) Coronal T2-weighted MR image.

because doing so will not increase the chance of cure enough to justify the risk for harm. The most valuable tool in the assessment of extent of resection is postoperative MR imaging because the surgeon's judgment is notoriously suspect.

41.2.2 Histologic Grading

There are numerous articles in the literature both supporting and refuting the value of histologic grading in determining the prognosis of patients with ependymoma.^{6,11,20,22,23,28-31} Anaplastic ependymoma exhibits histologic evidence of advanced anaplasia, including nuclear atypia, marked mitotic activity, a high level of cellularity, microvascular proliferation, and/or necrosis. Part of the reason for the controversy in the literature is the inability of pathologists to agree on what constitutes an anaplastic ependymoma. A study from the Children's Cancer Group (CCG) showed that 22 of 32 cases (69%) had a discrepancy in the diagnosis at the time of central pathologic review.¹¹ Ellison et al reported less than 50% agreement among five experienced neuropathologists across three multicenter studies of ependymoma. Four of five agreed only 70% of the time.³²

Analysis of a group of 50 contemporary patients with ependymoma from St. Jude Children's Research Hospital showed that tumor grade was significantly related to PFS after irradiation ($p < 0.001$).¹⁹ In this group of patients, 2-year event-free survival (EFS) was $32\% \pm 14\%$ for children with anaplastic ependymoma and $84\% \pm 7\%$ for children with classic ependymoma. This association remained significant after adjustment for ages less than 3 years, chemotherapy, and extent of resection. Supratentorial ependymomas were more likely than posterior fossa ependymomas to show anaplastic histology.

Recently, attempts at more simple risk stratification have been reported.³³ Gain of chromosome 1q and STR reliably placed patients into a high-risk category independently of histopathologic analysis. Cell density and mitotic count were used in the model to add specificity; however, mitotic count did stratify out an intermediate-risk category (► Fig. 41.3). It did not improve the prediction over 1q status and totality of resection alone.

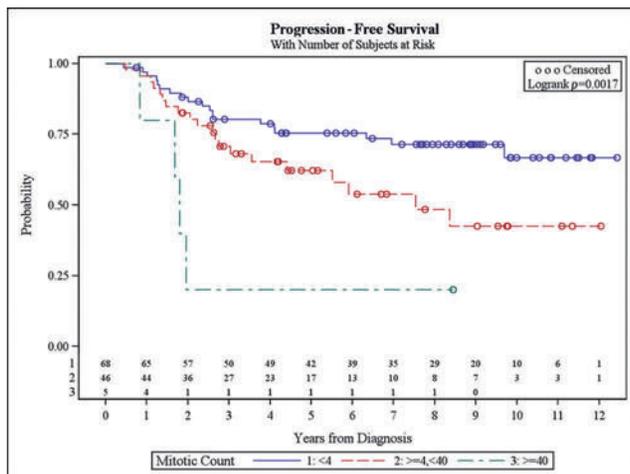

Fig. 41.3 Progression-free survival with number of subjects at risk. (Courtesy of David Ellison.)

41.2.3 Age at Diagnosis

Children less than 3 years of age at the time of ependymoma diagnosis have a poor prognosis when compared with older children. Several factors may account for this. Tumors in children of this age have a different molecular pathophysiology (see below) and may have more aggressive clinical behavior. Younger children are more fragile and have increased complications of surgery, radiation, and chemotherapy. Clinicians are reluctant to give radiotherapy to children less than 3 years old, or they give lower doses of radiation supplemented by chemotherapy. Pollock reported a 5-year survival rate of 22% and a PFS rate of 12% in children less than 3 years of age. Older children had 5-year survival rates of 75%, and the PFS rate was 60%.¹⁰ A study by the Pediatric Oncology Group (POG) showed a 63% 5-year survival rate for children 24 to 35 months of age (with radiation delayed 1 year by the use of chemotherapy), but only a 26% 5-year survival rate for younger children (0 to 23 months, radiation delayed 2 years).³⁴ The data of Merchant would suggest that the poorer prognosis in young children is more likely related to delayed or reduced-dose radiation. Historically, children who receive radiotherapy have had an increased survival compared with those who do not.^{35,36}

41.2.4 Pathology

Ependymomas are classified as glial tumors, and their diagnosis is often straightforward. Histologic grading is more difficult, and it is controversial, as discussed earlier. A pathologic diagnosis is made by histologic examination supplemented by immunohistochemistry. Ependymomas are moderately cellular neoplasms with monomorphic nuclei. Perivascular pseudorosettes and less commonly true ependymal rosettes can be seen on histology. Endothelial proliferation is seldom seen in classic ependymoma. The World Health Organization (WHO) classification defines grade II ependymoma as follows: mitoses rare or absent; occasional foci of palisading necrosis; nodules with increased cellularity, and mitotic activity.³⁷ Ependymomas usually stain positively for glial fibrillary acidic protein (GFAP).

Anaplastic ependymoma (AE) is a grade III lesion in the WHO classification.³⁷ Tumors with clear ependymal differentiation, perivascular pseudorosettes, increased cellularity, cytologic atypia, and microvascular atypia are diagnosed as AE. Areas of hypercellularity may be diffuse or focal and may form well-circumscribed regions. Additionally, areas of cytologic atypia, including an increased nuclear-to-cytoplasmic ratio and cellular pleomorphism, may be seen. Anaplastic regions often have a higher mitotic rate, although no specific threshold for a diagnosis of AE is in wide acceptance. The 2000 WHO criteria for AE include increased cellularity, brisk mitotic activity, vascular proliferation, and pseudopalising necrosis.³⁸ Neither focal areas of atypia nor brisk mitotic activity is sufficient to make a diagnosis of AE. It is unclear whether AE arises from progression or malignant degeneration of classic ependymoma or if it occurs de novo. Failure to find true ependymal rosettes or perivascular pseudorosettes is associated with a poor prognosis in children with ependymoma.¹⁷ Two separate groups have reported that the combination of necrosis, endothelial proliferation, and a mitotic index above 5 was a negative predictive factor for overall survival (OS) and PFS.^{17,39}

There is an inverse relationship between survival and mitotic rate demonstrated by proliferating cell nuclear antigen (PCNA), Ki-67, and MIB-1 labeling studies of ependymomas.^{17,25,39–41} However, one group found that mitotic rate was important only in determining the prognosis of supratentorial ependymomas.⁴²

Worse survival is related to increased expression of the following: p53, topoisomerase II- α , B-cell lymphoma-2 (Bcl-2), tenascin, vascular endothelial growth factor (VEGF), and epidermal growth factor receptor (EGFR).^{25,43,44} Nuclear expression of the apoptotic protein Survivin portends a good prognosis in breast and gastric cancer, and low levels of nuclear Survivin were seen with higher-grade ependymoma than with classic ependymoma.⁴⁵ Although these various molecular findings require further verification with prospective data, they may represent an additional opportunity to stratify ependymomas objectively, beyond the gain of chromosome 1q mentioned earlier, based on their biology.³³

There is mounting evidence that among the classic supra- and infratentorial and spinal ependymomas there are distinct cytogenetic differences that dictate their biology. These differences are likely based on differing progenitor cells or differentiation at different points during embryologic development. The group at St. Jude Children's Research Hospital has made significant advances in understanding the molecular basis of ependymomas. They used mRNA profiles to segregate ependymomas by central nervous system (CNS) location and unmasked previously unknown subgroups among supratentorial, posterior fossa, and spinal ependymomas, classifying ependymomas into nine distinct subgroups (subgroups A through I).¹ They identified potential ependymoma oncogenes, which included several regulators of stem cell proliferation, pluripotency, and neural differentiation. These include *THAP11*, *PSPH*, *EPHB2*, 10 genes within the *PCDH* cluster, *KCNN1*, *RAB3A*, *PTPRN2*, and *NOTCH1*. This finding allowed the researchers to create the first ependymoma mouse model. The specific combination of embryonic cerebral radial glial cells, deletion of *Ink4a/Arf*, and amplification of *EphB2* generated supratentorial ependymomas.¹

Researchers from Toronto and Heidelberg confirmed these findings in 2011 with a study that examined two independent cohorts of patients with posterior fossa ependymoma.² Using a combination of cytogenetic techniques, they grouped tumors into three distinct biological groups—a supratentorial ependymoma and two posterior fossa subtypes. The two posterior fossa subtypes were indistinguishable under the microscope. The groups were segregated into group A (younger, male, balanced genome, WHO grade III, CPA location, invasive, recurrent, metastatic, worse survival) and group B (older, gender-balanced, unbalanced genome, fourth ventricular location, rarely invasive, rarely recurrent, rarely metastatic, good survival). PFS and OS rates for group A were 44% and 65%, respectively. The corresponding rates in group B were 75% and 95%, indicating that although the tumors are histologically identical, they are distinctly different diseases. The investigators found group A tumors to be LAMA2+/NELL2- and group B tumors to be LAMA2-/NELL2+.

The ability to stratify ependymoma patients will allow clinicians to identify which of them will require more aggressive and/or novel therapies. Future clinical trials should include an

assessment of the status of these markers and their correlation with response to therapy, PFS, and OS.

41.3 Types of Ependymoma

There are several variants of ependymoma that have distinct histologic appearances or that exhibit unique biology. These ependymoma variants all show evidence of ependymal differentiation on electron microscopy; however, they likely represent entities that are distinct and separate from classic ependymoma. Thus, a collection of diseases exists that should be called the ependymomas.

41.3.1 Myxopapillary Ependymomas

This variant of ependymoma occurs in the filum terminale or conus (► Fig. 41.4) and in the adult literature is very indolent. In the pediatric literature, myxopapillary ependymomas are not so indolent; they are more likely to recur and to metastasize.^{46,47} Patients typically present with pain, lower extremity weakness, numbness, and bladder dysfunction.⁴⁸ The diagnosis is often delayed because of the nonspecific nature of the presentation.⁴⁹ Myxopapillary ependymoma appears on imaging as an extramedullary tumor, or as a tumor growing out of the conus (► Fig. 41.4). Compared with other spinal tumors, myxopapillary ependymomas can have a high signal on T1-weighted MR imaging, perhaps because of their high content of mucin.⁵⁰ Myxopapillary ependymomas in adults are cured with total excision. Less so in children. Subtotal resection followed by local radiation therapy is used to minimize neurologic deficits in cases in which the tumor is deemed unresectable.^{48,51,52} Uncommonly, myxopapillary ependymomas may metastasize, at which time they can be successfully treated with craniospinal irradiation, with the recognition that craniospinal irradiation in children is quite morbid.⁵³ As such, the authors feel strongly that incompletely resected myxopapillary ependymomas in children should not be observed but should be treated, either with return to surgery for GTR or with focal irradiation if unresectable. Histologically, the tumors appear as cuboidal cells arranged around a fibrovascular core with extensive areas of intrapapillary mucin. Myxopapillary ependymomas show a distinct biology; gains of chromosomal material on chromosomes 9 and 18 are seen in most tumors that are not commonly seen in classic ependymoma. It remains unclear what biological relationship (if any) myxopapillary ependymomas have to classic ependymomas.

41.3.2 Clear Cell Ependymomas

This ependymoma variant occurs preferentially in children and is usually found in the supratentorial compartment.⁵⁴ Histologically, it may be mistaken for other clear cell neoplasms, including oligodendroglioma, central neurocytoma, hemangioblastoma, and renal cell carcinoma.⁵⁴ Electron microscopy is invaluable in the diagnosis of this variant; it shows ependymal features, including microvilli, cilia, and junctional complexes.^{55,56} Cysts with enhancing walls were seen in 9 of 10 patients with clear cell ependymoma.⁵⁴ The

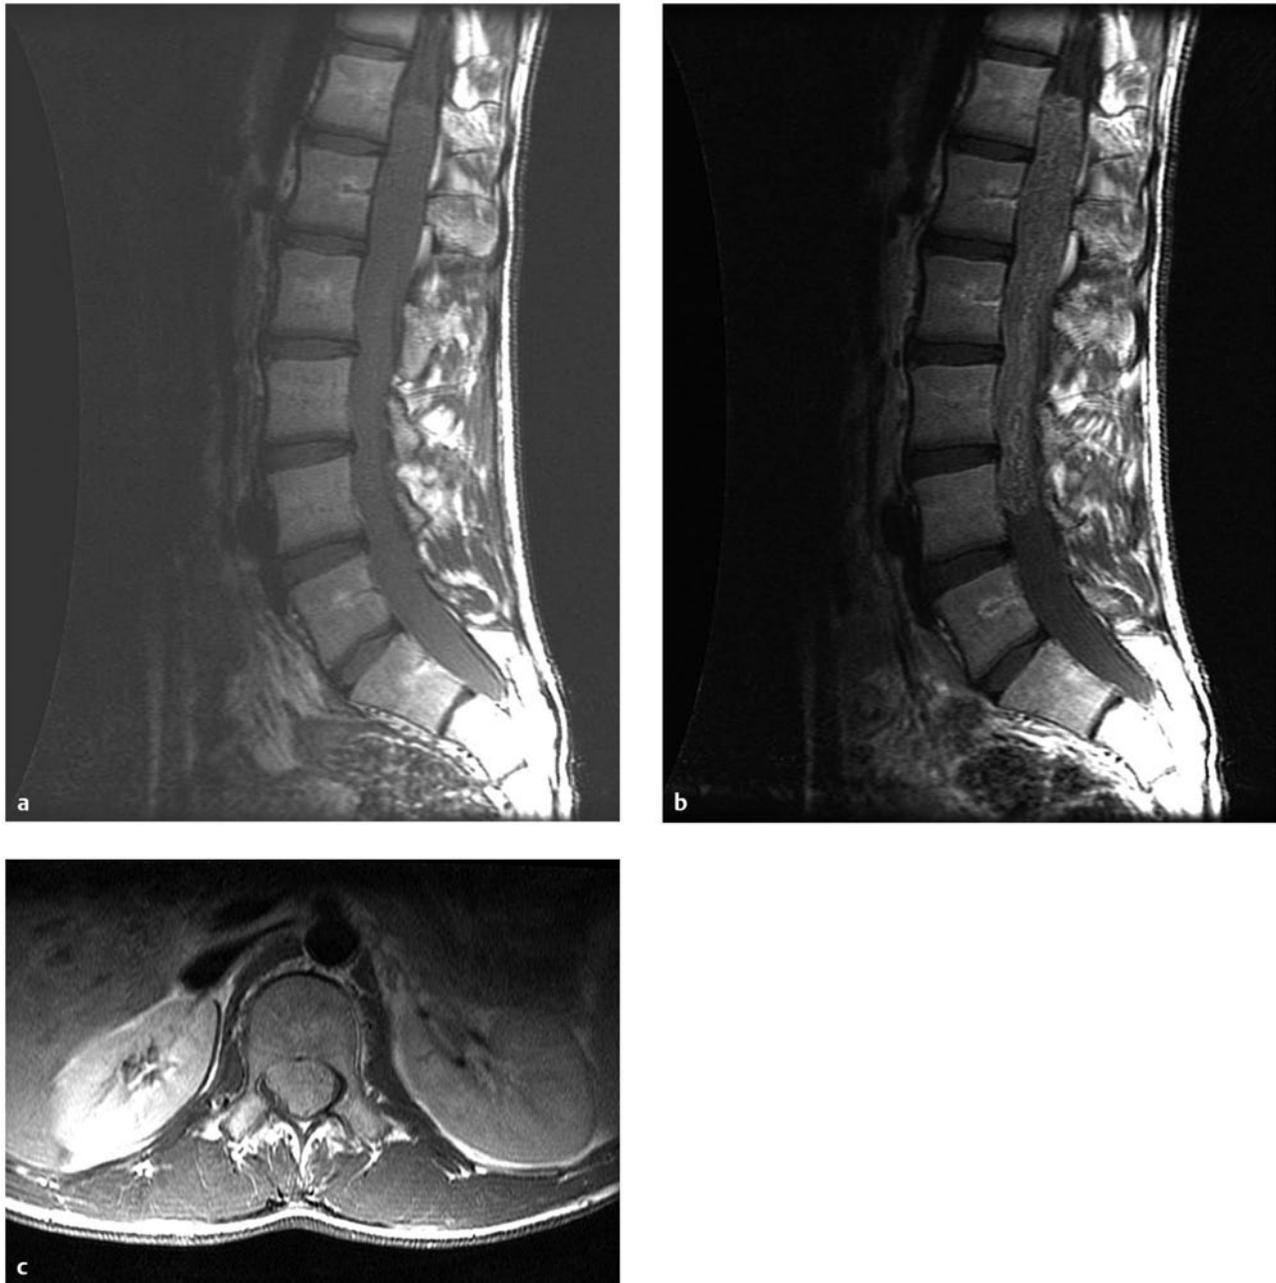

Fig. 41.4 Myxopapillary ependymoma in a child with back pain. (a) Sagittal T1-weighted magnetic resonance (MR) image without contrast shows an intradural tumor filling the thecal sac in the low thoracic and lumbar spine. (b) Added intravenous contrast better defines the tumor and shows that it extends from T12 to L4. (c) Axial image shows the tumor filling the thecal sac, displacing the nerve roots to the periphery of the sac.

PFS and OS rates at 5 years in a recent series of clear cell ependymomas were $34\% \pm 20\%$ and $75\% \pm 19\%$, worse than those for classic ependymoma.⁵⁴ In that series, 2 of 10 patients developed extra-CNS metastases.⁵⁴ Clear cell ependymomas showed frequent loss of genetic material on chromosome 18, a finding specific to the clear cell variant that is not commonly seen in classic ependymoma. These are probably biologically unrelated tumors.

41.3.3 Intramedullary Spinal Cord Ependymomas

Ependymomas within the spinal cord (► Fig. 41.5) typically present with myelopathy, back pain, weakness, bowel and/or bladder deficit, or scoliosis.⁵⁷ The presence of an intramedullary ependymoma of the spinal cord in a young child should prompt one to consider neurofibromatosis type 2 (NF-2).

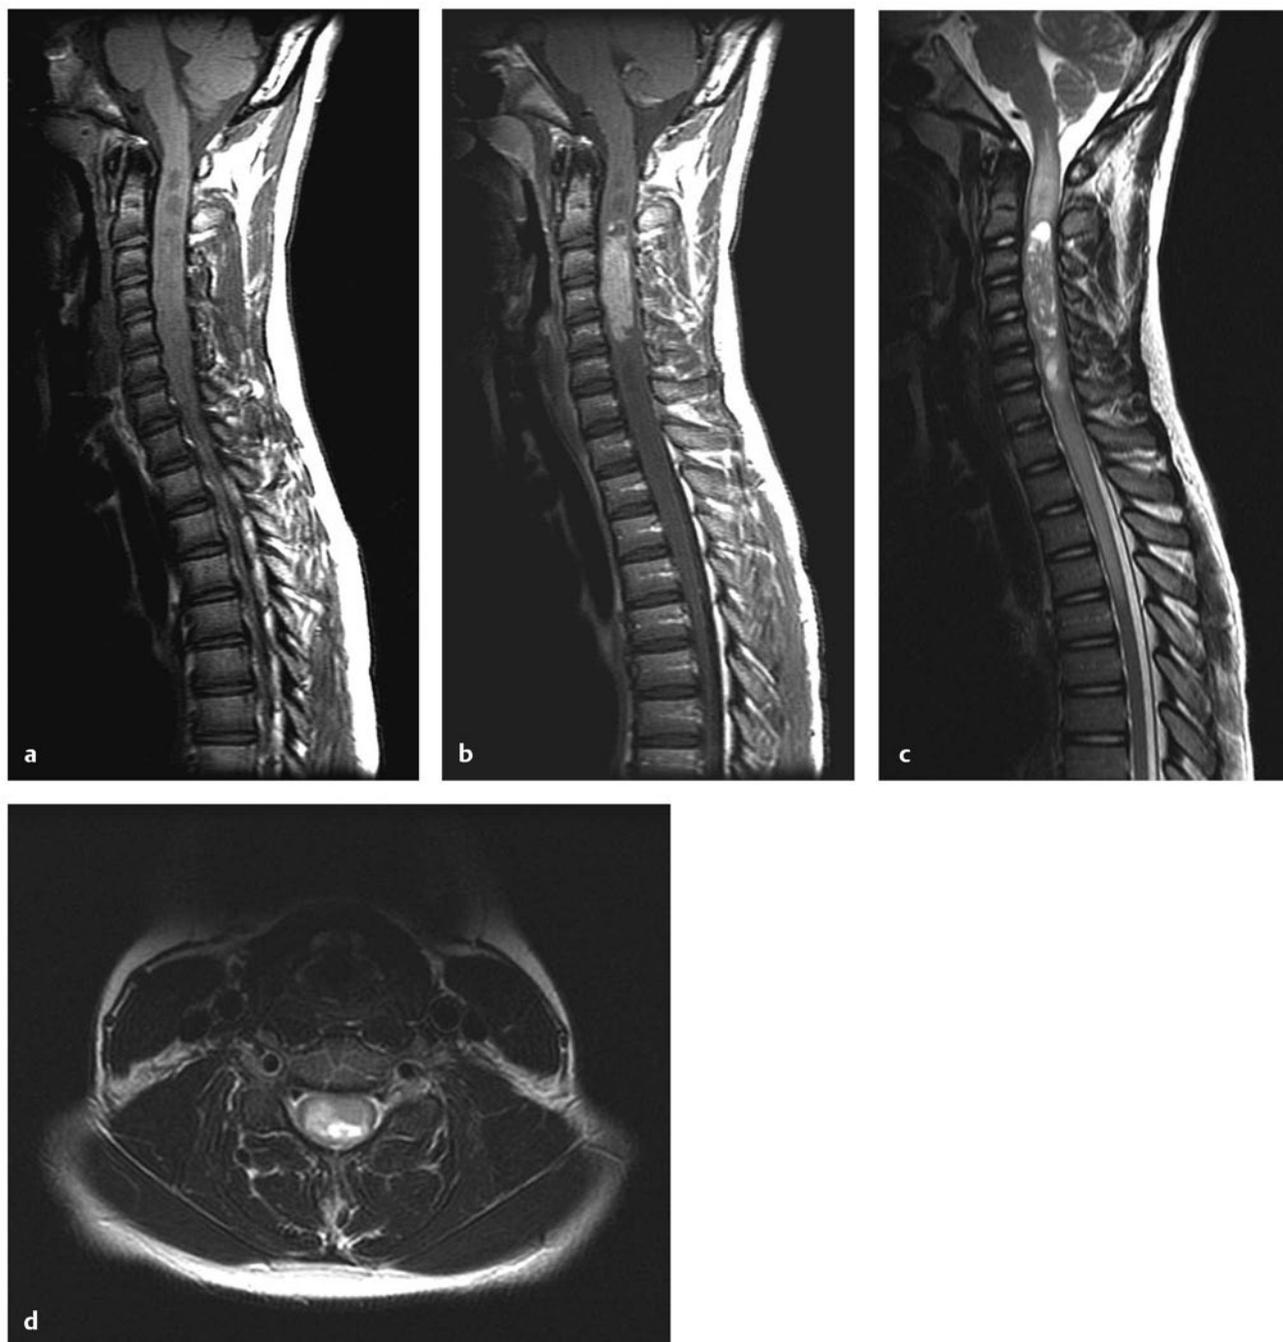

Fig. 41.5 (a) Cervical intramedullary ependymoma. (a) Sagittal T1-weighted magnetic resonance (MR) image without contrast shows areas of low signal within an expanded cervical spinal cord. (b) Sagittal T1-weighted MR image with contrast shows an enhancing mass lesion (ependymoma) within the cervical spinal cord. Cystic areas (syrinxes) are seen both superior and inferior to the mass lesion. (c) Sagittal T2-weighted MR image shows the intramedullary tumor and the adjacent syrinxes. Edema of the spinal cord is seen extending rostrally to the brain stem. (d) Axial T2-weighted MR image shows expansion of the cord with abnormal signal.

Intramedullary ependymomas are more discrete than intramedullary fibrillary astrocytomas and thus are easier to completely resect because of the presence of an obvious tumor–spinal cord interface. Current treatment for these rare tumors at St. Jude is maximal safe resection followed by focal radiotherapy.⁵⁸ Of only 4 patients with intramedullary ependymoma treated at St. Jude, 2 are dead of disease.⁵⁸ In a recent mixed

series of 67 adult and pediatric tumors, GTR was the stated preoperative goal, and when it was achieved (55 cases), no postoperative radiation was performed.⁵⁷ There were only 3 recurrences in the patients with initial GTR, and 2 underwent repeated operation for GTR. Radiation was reserved for patients in whom GTR was not achieved. Although intramedullary ependymomas are histologically similar to intracranial endy-

omas, they have a distinct biology. Patients with NF-2 are prone to developing spinal ependymomas. Moreover, sporadic intramedullary ependymomas, but not sporadic intracranial ependymomas, have somatic mutations of the *NF2* gene. This demonstrates that although intracranial and intraspinal ependymomas are histologically similar, they differ in biology and thus would be expected to have distinct natural histories and responses to therapy.

41.3.4 Tanycytic Ependymomas

Tanycytic ependymomas are an uncommon variant, with fibrillary cells that usually extend to the lumen of the ventricle.⁵⁹ They may occur within the brain or the spinal cord.^{59,60} True ependymal rosettes are absent, and perivascular pseudorosettes are sparse.⁵⁹ This ependymoma variant is often difficult to differentiate from an astrocytoma or a schwannoma. Immunohistochemistry is positive for GFAP and S-100.⁵⁹ This variant is thought to arise from tanocytes, a group of elongated unipolar and bipolar cells that extend between the ventricular lumen and the surface of the CNS. The ependymal nature of these tumors has been demonstrated based on their electron microscopy characteristics.⁵⁹ Although reports of tanycytic ependymoma are sparse, it should be recognized. It is likely an indolent variant, and aggressive therapies should be used with caution.^{59,60}

41.4 Genetics

Intramedullary spinal ependymoma is well known to occur in patients with NF-2; however, patients with NF-2 are not at increased risk for the development of intracranial ependymomas. Mutations of the *NF2* gene, located on chromosome 22q, are not found in intracranial ependymomas, myxopapillary ependymomas, or tanycytic ependymomas.^{61,62} Although intracranial ependymomas are well known to show loss of genetic material on 22q, they do not harbor *NF2* mutations, suggesting the existence of another, distinct ependymoma tumor suppressor gene in this region of the genome.

Classic ependymoma is reported in patients with the Li-Fraumeni familial cancer syndrome (*TP53* tumor suppressor gene).^{63,64} However, somatic mutations of *TP53* are not commonly found in sporadic ependymomas and likely do not play a large role in their pathogenesis.^{65,66} Scattered reports of patients with ependymoma and Turcot syndrome (brain tumors plus colonic neoplasia) are found in the literature, with some patients developing more than one ependymoma.⁶⁷⁻⁶⁹ These patients have germline mutations in the adenomatous polyposis coli (*APC*) gene on chromosome 5 and have overactivity of the Wnt signaling pathway. The role of the *APC* gene and/or Wnt signaling in sporadic ependymomas has not been elucidated. Spinal ependymomas have also been reported in the context of the multiple endocrine neoplasia type 1 syndrome due to mutation of a tumor suppressor gene on chromosome 11q13.^{70,71} Other families have an increased incidence of ependymomas, but no currently recognized familial tumor syndrome has been reported.⁷²⁻⁷⁴

41.4.1 Cytogenetics

As a group, ependymomas studied by G-banding karyotype show a frequent loss of genetic material on chromosomes 22q,

6q, 9q, 17p, and 11q and show a gain of genetic material on chromosome 1q.^{62,64,75-80} Loss of heterozygosity on chromosome 22q is more common in adult ependymomas and intramedullary spinal ependymomas and less common in pediatric ependymomas.⁶⁴ There is some evidence that the gain of genetic material on chromosome 1q may be an early event in the initiation of ependymoma.⁷⁵ A 1q gain stratifies patients into a higher-risk group.³³ Subsequently, several groups have published studies in which the technique of comparative genomic hybridization was used to study ependymomas.⁸¹⁻⁸⁷ This technique is more sensitive than a G-banding type karyotype at finding gains and losses of genetic material. Ependymomas from very young children frequently show a balanced karyotype (no observed gains or losses).⁸¹ Classic ependymomas from the brain and those from the spine have different cytogenetic profiles. Tumors with gain of chromosome 1q tend to occur in the posterior fossa in children, and the tumors often behave aggressively.⁸¹ Recurrent tumors show more extensive karyotypic abnormalities than the original tumors; whether this is due to biological progression or to random DNA damage from radiation and/or chemotherapy is not clear.⁸² Myxopapillary ependymomas show a higher number of cytogenetic abnormalities (average of nine per tumor) than do other ependymomas.⁸⁵ The most common changes seen in cases of classic ependymoma are gains of chromosomal material on chromosome arm 1q or chromosome 9 and losses of 6q, 22, and the X chromosome.⁸⁴

41.5 Imaging Studies

MR imaging is central to the diagnosis, management, and follow-up of children with ependymoma. Anatomical definition is required before surgery to determine the extent of tumor growth because some ependymomas have a propensity to grow out of the foramen of Luschka into the CPA or out of the foramen of Magendie into the cervical spine. MR imaging is also used to plan radiotherapy and to judge response to chemotherapy when it is given. Rarely, a child may present in extremis, and an operation will be done without preoperative MR imaging.

Most children with ependymoma should have pre- and postoperative imaging of the brain, and either pre- or postoperative imaging of the entire spine. Postoperative brain imaging should be done within 72 hours of surgery because after this time postsurgical artifact may make it difficult for radiologists to determine the extent of resection. If this 3-day window is missed, MR imaging should be delayed for a couple of weeks, at which time the artifact from surgery is decreased. Gelfoam (Pfizer, Cambridge, MA and La Jolla, CA) or Surgicel (Johnson & Johnson, New Brunswick, NJ), used for hemostasis at the time of surgery, can make the postoperative images difficult to interpret and may enhance over time, causing confusion with recurrent tumor. Leaving such material in the wound is therefore strongly discouraged.⁸⁸

Most ependymomas are variably enhancing. The T2 image helps determine the true extent of the tumor. Pre- and postoperative T1 films with and without gadolinium enhancement, as well as T2-weighted imaging, are necessary for comparison. Both the location and the extent of residual tumor are important in formulating a therapeutic plan.

The optimal frequency of surveillance imaging after treatment of ependymoma is uncertain. Most children with recurrence or progression present between 12 and 24 months after the initiation of radiation therapy. Early detection of recurrence should maximize the opportunity for salvage therapies. Some retrospective trials suggest that the early detection of asymptomatic recurrence of ependymoma leads to better outcomes than diagnosis when the recurrence becomes symptomatic.^{89,90}

Preoperative spinal imaging identifies patients (approximately 5%) who present with leptomeningeal dissemination. Subsequent surveillance imaging of the spine is problematic because there are many mimics of leptomeningeal disease, including blood products, infection, and inflammatory changes secondary to surgery or radiation therapy. Any spinal imaging that cannot be performed before surgery should be performed at least 7 to 10 days after any invasive CNS procedure. Leptomeningeal tumor usually appears as a series of small nodular tumors, or as thick disease coating the subarachnoid space focally. Diffuse “sugar coating,” such as that seen in medulloblastoma, is seldom seen in ependymoma, and leptomeningeal should not be diagnosed if there have been any recent invasive procedures on the CNS.

Complete responses to either radiation or chemotherapy are uncommon in children with ependymoma, although partial responses are often seen. After radiation, most ependymomas will diminish in size over a period of years and many show loss of contrast enhancement due to a loss of vascularity. Conversely, some ependymomas may show an increase in enhancement for the first several months after radiation because of an increase in leukocyte–endothelial interactions. This should not be misinterpreted as progression of the tumor. Recurrences in the first year after adequate radiation therapy are uncommon. Similarly, responses to chemotherapy manifest approximately 6 months after the start of treatment.

41.6 Surgical Treatment

Most children with ependymoma present with localized disease. Most recurrences are local. Subarachnoid dissemination is rare and fatal. This disease is well suited to therapies designed to achieve local control. The overriding value of GTR of ependymoma has been demonstrated in several institutional retrospective reviews and two prospective Phase III trials.^{4–7,9–11,20,23,34} Ependymoma is a surgeon’s tumor because this portion of the patient’s care has the highest impact on the quality and quantity of life.

Sutton et al retrospectively analyzed 45 patients with ependymoma and found that the 5-year survival for GTR or NTR was 60%, but with STR (defined here as <90% resection), it fell to 21%.⁷ Pollack et al found a 5-year survival rate of 80% after GTR, compared with 22% after less than GTR.¹⁰ Sutton et al retrospectively evaluated 92 children with ependymoma; the 10-year survival after GTR was 70%, and the PFS estimate was 57%.⁶ With STR, the 10-year survival was 32% and the 10-year PFS was 11%. Robertson et al prospectively treated 32 patients with CCG protocol 921 and found that the 5-year PFS rates were 66% for patients with less than 1.5 cm² of residual tumor and 11% for those with more tumor.¹¹ There is overwhelming evidence that cytoreductive surgery is beneficial to children with ependymoma and gives the best chance for long-term survival.

Two groups reported surgery without adjuvant treatments (i.e., radiation or chemotherapy) for children with ependymoma.^{21,88} Hukin et al described 10 pediatric patients who received only surgery as treatment for ependymoma; 8 tumors were supratentorial and 2 were in the posterior fossa.⁸⁸ At a median of 48 months of follow-up, 7 of the 10 patients were free of disease without having received adjuvant therapy. The other 3 patients had documented tumor recurrence at 9, 10, and 20 months after resection. Of the 3 patients, 2 were effectively treated with repeated surgery and radiation. Of the other 7 patients, another 2 went on to late failures. Little et al argued that deferring radiation in low-risk patients (older than 3 years, GTR, focal disease, lack of high-grade features) was a reasonable option.⁹¹ Palma et al reported success in treating supratentorial ependymomas with surgery alone.²¹ Surgery alone is probably a reasonable therapeutic option for children with supratentorial ependymoma with low-grade histology when the surgeon is able to take a rim of white matter around the tumor.

Although complete resection is of paramount importance in the treatment of ependymoma, it is achieved in only 42 to 70% of patients at initial resection.^{5,7,10,23,92} Complete resection is more readily achieved in supratentorial tumors and those that arise from the roof of the fourth ventricle. GTR of tumors that invade the floor of the fourth ventricle or pass out the foramen of Luschka to involve the lower cranial nerves is much more difficult, and surgical complication rates are higher.

41.6.1 Treatment of Residual or Recurrent Ependymoma

Most children who initially receive less than an NTR should have repeated surgery to reduce their status to minimal residual disease (GTR or NTR) (► Fig. 41.6). The exception to this may be those rare cases in which resection of the residual tumor will result in intolerable morbidity. In the case of surgery that is abandoned because of excessive bleeding, chemotherapy between resections may decrease the vascularity of the tumor, thus facilitating a safe return for repeated resection.⁹³ An evaluation of the initial approach may make obvious why the initial resection was STR. An alternate approach may make previously “hidden” tumor easy to resect. Second resections for ependymoma have an acceptable morbidity.²⁶ Although some complications were seen in 45% of children undergoing second-look surgery for pediatric CNS tumors, there was no significant change in mean functional scale scores at 4 or 24 weeks after surgery.⁹⁴ Foreman et al achieved GTR in four-fifths of a group of patients with ependymoma at the time of second surgery with no severe morbidity, and three of the patients remained progression-free at 23, 25, and 34 months after radiation therapy.²⁶

Recently, Massimino et al reported a progressive policy of second-look surgery in a multicenter trial. GTR rates for the entire group increased by 10 to 15% and by more than 50% in those undergoing second operations. They reported no additional major morbidity. The authors suggest that referral of these children with complicated cases to high-volume pediatric neurosurgery centers for their second-look surgery may improve outcomes.²⁷

In a series of 40 pediatric patients with ependymoma referred over a 3-year period at St. Jude Children’s Research

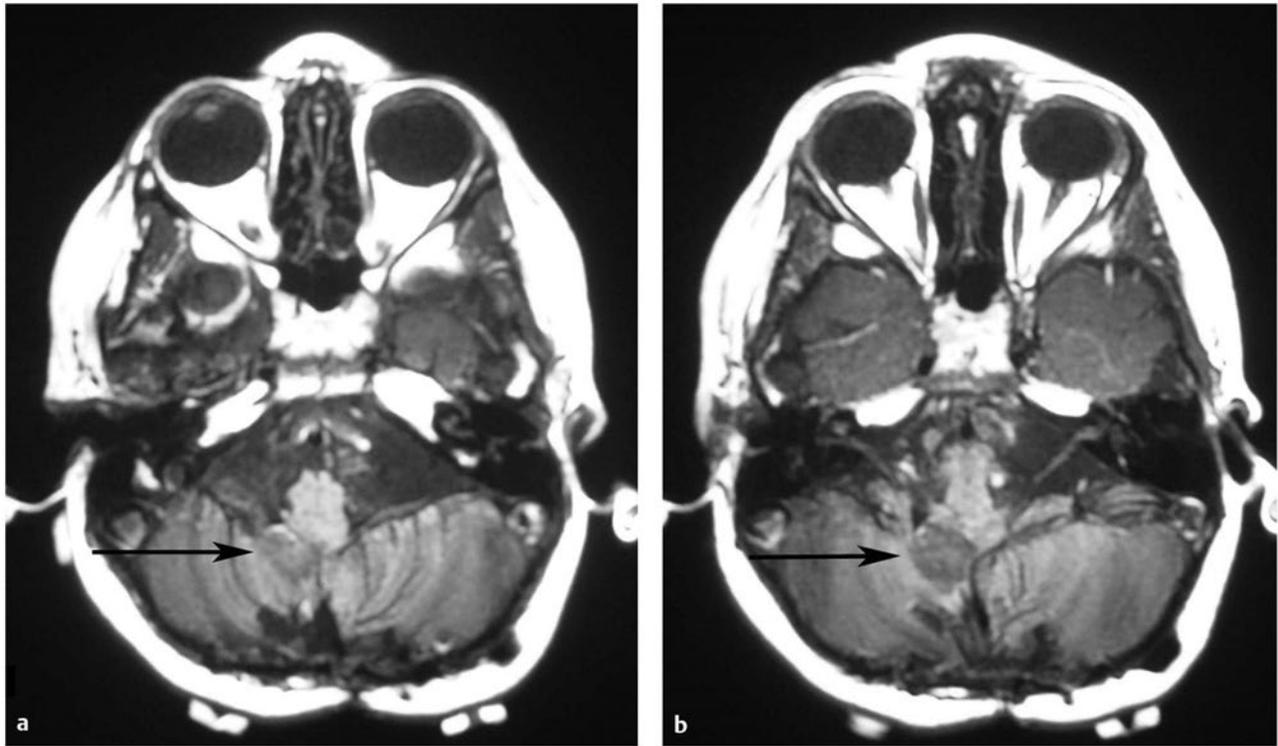

Fig. 41.6 Residual ependymoma after a first resection. (a,b) Postoperative magnetic resonance images after resection of a pediatric posterior fossa ependymoma show a small amount of nonenhancing residual tumor in the right foramen of Luschka. This residual tumor was resected at a repeated craniotomy, yielding a gross total resection.

Hospital, 24 of 40 patients (60%) had undergone complete resection, and 16 of 40 patients (40%) had residual tumor at the time of referral. Of those 16 patients with residual tumor, 12 were selected to receive additional surgery based on extent of disease, location of disease, and neurologic status at the time of referral. Of those 12 patients, a GTR was achieved in 10 and an NTR in the other 2 at the time of the second surgery; hence, the GTR–NTR resection rate for the entire cohort was 36 of 40 (90%). Successful GTR at the time of second-look surgery may prolong survival time as well as allow a lower dose of radiation to be used, thereby lowering the incidence of neurocognitive deficits.⁹⁴ Significant morbidity occurred in only one child at the time of second resection. Children who underwent repeated surgery within 30 days of the initial procedure had an improved performance level at 4 and 24 weeks after second surgery and a trend toward a lower complication rate compared with children who had second look surgery more than 30 days after the initial procedure.⁹⁴

Children with localized recurrent disease that is amenable to surgical resection should undergo repeated resection (► Fig. 41.7). If needed, referral to a high-volume pediatric neurosurgery center should be considered to maximize the chances of GTR without an increase in morbidity.

41.6.2 Surgical Technique

Careful preoperative scrutiny of the imaging is necessary to determine the extent of the tumor because ependymomas are notorious for extension through the foramen of Luschka out into

the CPA. Moreover, they often extend down through the foramen magnum into the upper cervical spinal canal. After adequate imaging interpretation, the goals of, and appropriate approach to, surgery will be decided. Interpreting ependymoma imaging can be difficult, given that there may be variable enhancement within the tumor. The T2 image and the FLAIR (fluid-attenuated inversion recovery) image often demarcate the extent of the tumor better than the T1 image. The preoperative imaging characteristics are important when postoperative imaging is interpreted, especially in the presence of residual or recurrent disease.

Childhood ependymomas can be functionally and molecularly divided into supratentorial, posterior fossa, and spinal tumors. The surgical management of supratentorial ependymomas is usually straightforward because the tumor is very distinct from the surrounding normal brain. Frameless stereotaxy localizes the scalp incision directly over the tumor. In areas of noneloquent brain, a thin rim of normal white matter should be resected around the ependymoma to ensure a complete resection. Ependymomas normally do not contain functioning neural tissue and can be resected safely from areas of eloquent cortex. Supratentorial ependymomas that are located entirely within the ventricles are rare. Many supratentorial ependymomas abut or compress the ventricle without entering the ventricle (► Fig. 41.2).

Preoperative surgical planning should classify a posterior fossa ependymoma as arising from one of the following:

- Cerebellar hemisphere
- Roof of the fourth ventricle

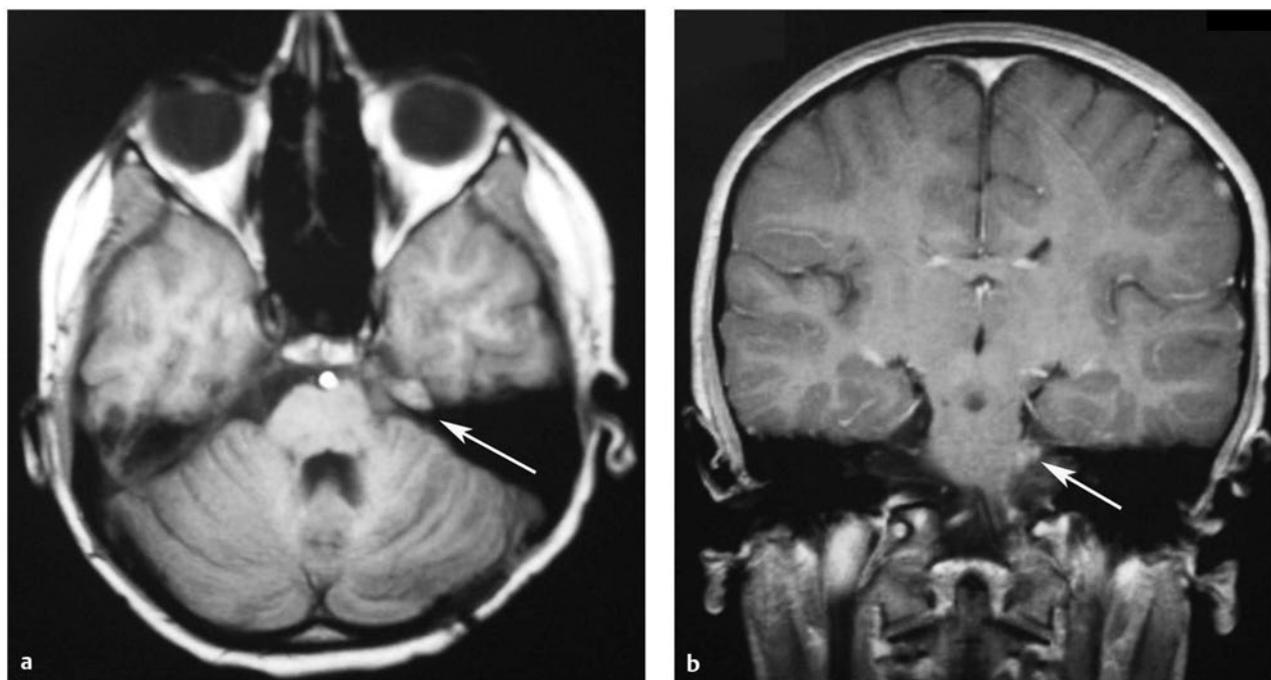

Fig. 41.7 Asymptomatic, recurrent ependymoma discovered on routine imaging. (a, b) This child with previous gross total resection and radiotherapy of a posterior fossa ependymoma was followed with routine magnetic resonance imaging. An asymptomatic recurrence was found in the left cerebellopontine angle, adjacent to the brainstem (*white arrows*). This was resected, and the child was treated with focal radiotherapy.

- Floor of the fourth ventricle
- Cerebellopontine angle (► Fig. 41.8)

Each location will dictate a different surgical strategy and entail a different set of surgical risks.

The patient is positioned prone with maximal tolerated flexion so that the floor of the fourth ventricle is sloping away from the surgeon. In the presence of hydrocephalus, a ventriculostomy may be placed before the posterior fossa is opened. The surgeon should release CSF slowly so as not to precipitate upward herniation or shifts in the tumor with consequent intratumoral hemorrhage. Craniotomy, as opposed to craniectomy, decreases the incidence of CSF leak and/or pseudomeningocele, and also diminishes the incidence of chronic postoperative pain.⁹⁵ The presence of a bone flap also facilitates surgery for residual and/or recurrent ependymoma. An appropriately sized craniotomy should be planned and executed based on the anatomy of the tumor. If needed, a C1 laminectomy is performed. The foramen magnum should be removed so as to increase exposure and to open pathways for CSF flow.

The dura is opened in a standard Y-shaped fashion. One should anticipate robust bleeding from an occipital and circular sinus and be prepared for management. If the dura over the cerebellum is tight, the dura over the upper cervical cord can be incised to allow the slow egress of CSF and relaxation. Alternatively, CSF can be withdrawn through a previously placed ventriculostomy. After the dura is opened, the cerebellar tonsils are separated to identify the posterior inferior cerebellar arteries. The vascular supply to a midline fourth ventricular tumor invariably comes off of the posterior inferior cerebellar artery

(PICA), distal to the tonsillar loop. Coagulation of large feeders to the tumor from the PICA devascularizes the tumor and results in a less bloody field.

Attention is next turned to the superior pole of the tumor, to define its margin circumferentially and then debulk it as it becomes devascularized. This continues until the aqueduct is visualized, opened, and covered with Gelfoam so as to prevent bleeding into the supratentorial ventricles, whereupon attention is turned to the inferior pole of the tumor. The inferior pole is dissected along its lateral and posterior margins, with care taken not to injure the floor of the fourth ventricle. At this point in the operation, it is often possible to determine if the tumor is arising from the roof or the floor of the fourth ventricle. If the tumor arises from the roof, complete excision is possible. The lateral margins of the tumor are dissected to diminish the tumor blood supply; then the tumor is debulked with either the bipolar suction technique or the ultrasonic aspirator.

Once the entire tumor has been removed, except for the portion invading the floor of the fourth ventricle, the surgeon should attempt to visualize the floor of the fourth ventricle both above and below the remaining tumor. The tumor should be resected down to the plane of the floor of the fourth ventricle. One should not chase bleeding below this line.⁹⁶ Judicious use of hemostatic products, mild tamponade, irrigation, and time will stop the bleeding. This technique usually results in minimal morbidity while leaving minimal residual tumor. Injury to this area through the overzealous use of bipolar cautery can cause permanent cranial nerve palsies as well as damage to the medial longitudinal fasciculus. At the end of the procedure, it is critical to look out the foramen of Luschka bilaterally to avoid missing a small piece of tumor.

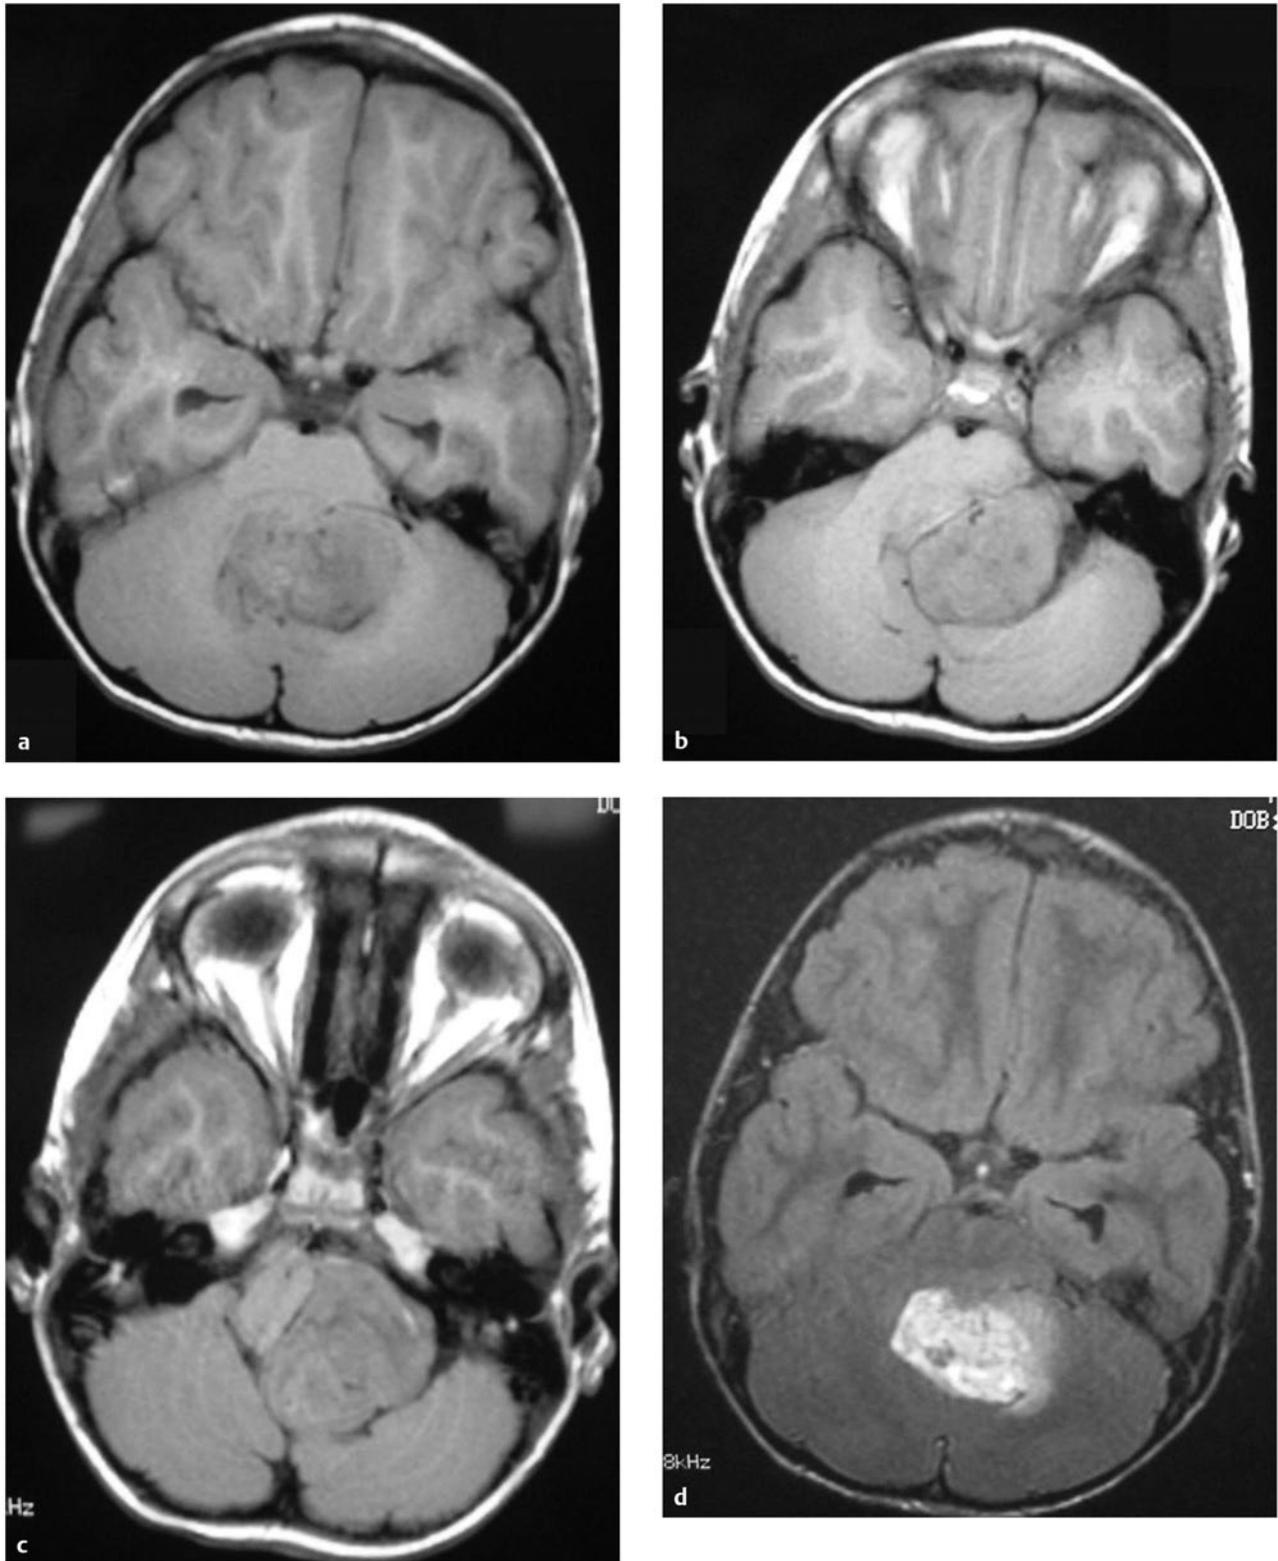

Fig. 41.8 A 7-year-old with 4 weeks of headache and vomiting. (a) An unenhanced T1-weighted magnetic resonance (MR) image shows a low-signal mass lesion within the fourth ventricle with extension into the cerebellopontine angle (CPA). (b) The extra-axial component of this tumor has severely compressed the brainstem and displaced it to the right. The anatomy of the displaced, rotated brainstem can be very confusing at the time of surgery. (c) Axial T1-weighted MR image with gadolinium shows enhancement of the lesion in the fourth ventricle. (d) The enhancing mass extends out of the foramen of Luschka. (*continued*)

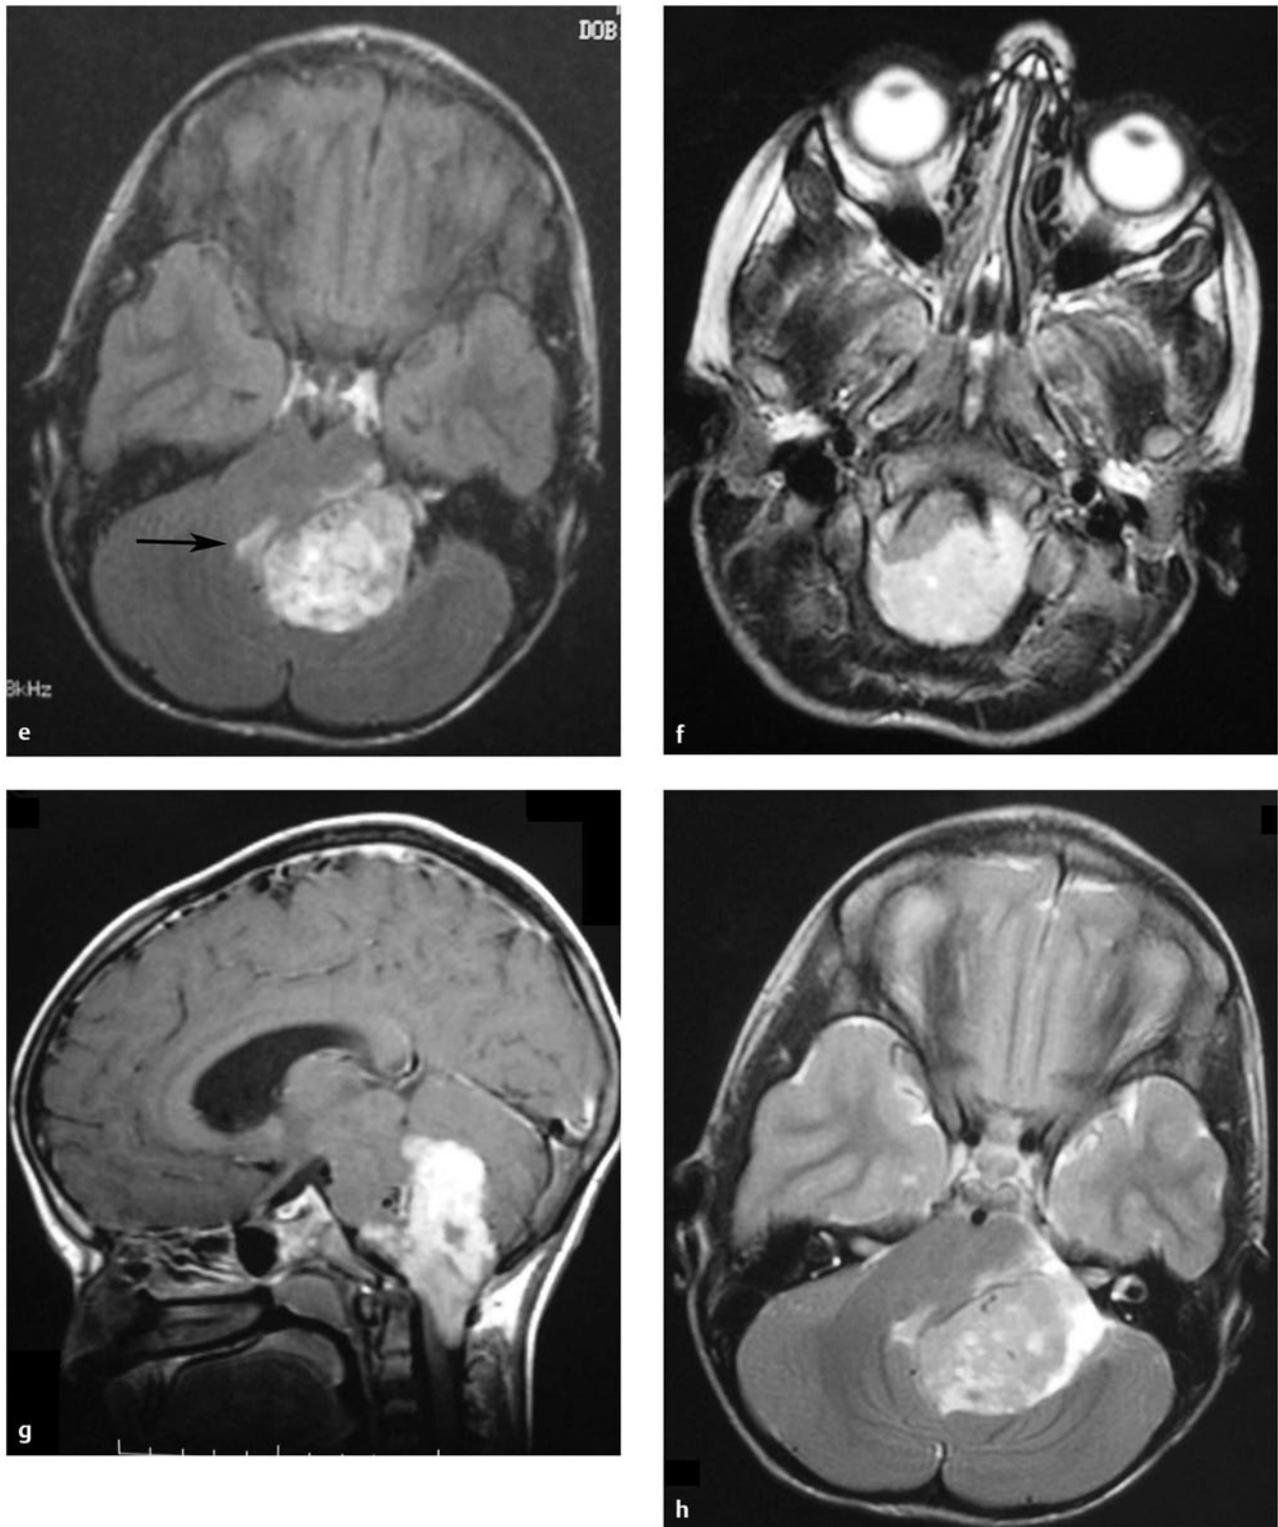

Fig. 41.8 (continued) (e) Partially enhancing, partially nonenhancing tumor around the lower brainstem. (f) Sagittal T1-weighted MR image with gadolinium shows enhancing tumor extending out into the CPA, as well as extending down into the cervical spinal canal. (g) Axial T2-weighted MR image shows a hyperintense lesion extending out of the foramen of Luschka on the left. (h) Axial T2-weighted MR image shows the mass effect on the brainstem, with the tumor, extending up to the basilar artery.

Care should also be taken to free the cerebellar tonsils and open the CSF flow pathways. Patch grafting of the dura may also help to open the CSF flow pathways and reduce the need for future shunt surgery. The bone flap is replaced.

CPA ependymomas originate from the lateral wall of the brainstem at the junction of the pons and the medulla (► Fig. 41.8). Their slow growth allows them to envelop multiple cranial nerves at the time of diagnosis (cranial nerves V through XII are at risk). Unilateral growth rotates the brainstem, distorting the normal anatomy and disorienting the surgeon. CPA ependymomas can grow through the foramen of Luschka into the fourth ventricle, filling it with tumor.

Like all posterior fossa ependymomas, CPA ependymomas have a blood supply from the PICA, with frequent contribution from the anterior inferior cerebellar artery (AICA), which runs through the CPA cistern. CPA ependymomas are often large by the time they come to clinical attention, and they predominantly occur in infants, making blood loss a major issue in their treatment. Transfusion should be planned for. High blood levels of potassium from the excessive transfusion of unwashed red blood cells in a very young child is unfortunately a cause of mortality.

Unlike many posterior fossa tumors, CPA ependymomas can often be diagnosed on preoperative imaging. Their removal is associated with very high rates of morbidity and mortality, even in experienced hands, and should be attempted only by surgeons who have experience with these tumors. Removal is accomplished by positioning the patient prone or in a park bench position with the head rotated so that the lateral portion of the cerebellum is highest. A far lateral craniotomy is performed. Knowledge of the vertebral artery anatomy is key in dissecting out laterally with the head rotated. The bone is opened along the sigmoid sinus, with removal proceeding as close to the jugular foramen as possible. If necessary, a C1 hemilaminectomy is performed. The dura is opened and the intraspinal portion of the tumor is removed first, with care taken not to injure the spinal roots. With the spinal portion removed, the vertebral artery and its PICA branch can be dissected free. The tumor is then debulked laterally until cranial nerves IX and X are identified entering the jugular foramen. Cranial nerves VII and VIII are identified in the CPA, and tumor is dissected away from them. A frequent cause of deafness after this operation is probably inadvertent sacrifice of the labyrinthine artery. This can be significant in children who may go on to receive ototoxic chemotherapy. After identification of the cranial nerves, the portion of the tumor within the fourth ventricle, which is generally not stuck in these cases, is removed before the lateral portion. This is accomplished by dividing the ipsilateral tela choroidea and inferior medullary velum such that the ipsilateral tonsil can be lifted up all the way to the foramen of Luschka. This allows a clear, unobstructed view of the entire fourth ventricle and ipsilateral foramen of Luschka. Once there is sufficient room in the posterior fossa, the most difficult part of the operation, removal of the tumor from the lower cranial nerves, is attempted. All feeding arteries originating from the major arteries and entering the tumor must be assumed to be brainstem perforating vessels until proven otherwise. These vessels must be preserved, or an unforgiving brainstem perforator stroke is possible.⁹⁶

Cranial nerve morbidity is high following removal of a CPA ependymoma. Children are maintained intubated until the vocal cords can be checked by an otolaryngologist. Vocal cord paralysis, when present, should be unilateral. Complete unilateral vocal cord paralysis in children who cannot handle their secretions mandates a tracheostomy. If there is some vocal cord movement, most children can be safely extubated and closely observed. Speech therapists should always perform swallowing studies on these patients.⁹⁷

It is not uncommon for a child to be able to manage his or her secretions (not require a tracheostomy) but still require a gastrostomy. Although many children have palsies of cranial nerves VI, VII, IX, and/or X postoperatively, more than 90% will recover within 3 to 6 months. Most children who initially require a tracheostomy or a gastrostomy will be able to have it removed during their convalescence.

One further complication of surgery for CPA ependymoma is that of residual tumor on postoperative imaging. In almost all cases, this should lead to a reoperation to achieve a GTR.

41.7 Treatment of Hydrocephalus in the Child with Ependymoma

Many children with ependymoma have hydrocephalus at the time of presentation, particularly those whose tumor is in the posterior fossa. Most neurosurgeons treat such children with corticosteroids until elective surgery can be performed. Preoperative shunting takes control of CSF drainage out of the surgeon's hands, with the recognized dangers of overdraining a child with a posterior fossa tumor (upward herniation and bleeding into the tumor due to brain shift). Those children who present in extremis may be treated with a ventriculostomy followed by definitive surgery to address both the tumor and the hydrocephalus.

Hydrocephalus is common in patients with posterior fossa ependymoma; however, it is much less common in patients with supratentorial ependymoma. Rarely, hydrocephalus may be seen in the setting of a spinal ependymoma as the consequence of high CSF protein levels secreted by the tumor. Hydrocephalus secondary to a posterior fossa tumor is due to occlusion of the fourth ventricle/aqueduct. In most children, removal of the fourth ventricular tumor, opening the aqueduct, and ensuring good flow of CSF at the level of the foramen magnum will restore CSF dynamics.

Postoperative hydrocephalus is rarely acute; more often, it develops slowly over a period of days or even weeks. The presentation is often the appearance of a pseudomeningocele or headache, nausea, vomiting, and lethargy. At times, postoperative hydrocephalus may be confused with posterior fossa syndrome. Asymptomatic, nonprogressive ventriculomegaly after fourth ventricular tumor excision should be observed over time rather than treated. In a child with symptomatic and/or progressive ventriculomegaly, treatment of the hydrocephalus is warranted. We favor an endoscopic third ventriculostomy as the initial hydrocephalus treatment unless the child has metastatic disease. If this is unsuccessful, a traditional shunt is placed. Both techniques have advantages and disadvantages that are beyond the scope of this chapter.

41.8 Adjuvant Therapy

41.8.1 Radiation Therapy

Postoperative radiation has been part of the standard therapy for patients with ependymoma since Mork and Loken showed that survival was 17% for patients who underwent resection alone, compared with 40% for those who underwent resection and radiation.³⁵ It may be acceptable to withhold radiation therapy in children with supratentorial ependymoma in whom a GTR has been achieved and in whom the pathology is classic WHO grade II ependymoma.^{35,72} There is little evidence to support radiation after GTR of an intramedullary spinal cord ependymoma.

A great deal of literature has focused on the dangers of radiation therapy in patients less than 3 years old with ependymoma. Numerous strategies to avoid or delay radiation have been proposed in this patient cohort in an attempt to minimize neurologic, endocrinologic, and cognitive morbidity. Although the side effects of administering radiation to very young patients with ependymoma have not been well documented, they are assumed to resemble those seen in infants with medulloblastoma, which are known. The POG-8633 study showed that young children with completely resected ependymoma in whom radiation was delayed for 2 years had a worse outcome (5-year survival, 38%) than did those children in whom radiation was delayed only 1 year (5-year survival, 88%).³⁴ Massimino et al reported the results of the AIEOP (Associazione Italiana Ematologia Oncologia Pediatrica) study, in which radiation therapy was deferred until age 3.⁹⁸ They found that survival was poor (overall survival rates of 48%, 37%, and 28% at 3, 5, and 8 years, respectively). They found no difference between the intellectual outcome of children receiving radiation at an age younger than 3 years and that of children with deferred radiation. These results suggest that delaying radiation in the treatment of focal ependymoma of infancy is not advisable.

Fewer than 5% of children with ependymoma have disseminated (leptomeningeal) disease at the time of diagnosis. Risk factors for dissemination include younger age, less than a GTR, a high proliferative index, and high-grade histology.⁹⁹ In most children with ependymoma who relapse, the relapse occurs at the primary site regardless of location or grade of the tumor.^{4,6,7} Multiple retrospective trials have failed to show the benefit of prophylactic craniospinal irradiation in the treatment of localized ependymoma.^{5,16,100,101} In light of these facts, the current recommendation at St. Jude Children's Research Hospital for nondisseminated ependymoma is localized radiotherapy. Craniospinal radiotherapy is reserved for children with leptomeningeal dissemination.

The radiation dose response level for ependymoma ranges from 45 to 60 Gy (gray), but the optimum dose of radiation remains unclear.¹⁹ Children with an STR (cannot benefit from further surgery) may benefit from dose escalation and/or hyperfractionation. Conformal radiation therapy (CRT) limits the highest dose of radiation to the primary tumor site (as opposed to administering radiation to the entire posterior fossa, for example) and decreases the dose received by normal tissues (especially the inferior portion of the temporal lobes). The role of CRT in the treatment of children with ependymoma was tested in a Phase II trial from 1997 to 2003 at St. Jude Children's

Research Hospital.¹⁹ Patients with localized ependymoma were evaluated before and after CRT to determine its neurologic, endocrine, and cognitive effects. Eighty-eight children (median age, 2.8 years) received irradiation therapy: 59.4 Gy in 73 patients and 54.0 Gy (age younger than 18 months and GTR) in 15 patients. GTR had been achieved through one or more craniotomies in 74 patients before irradiation, NTR in 6 patients, and STR in 8 patients. This study showed excellent results at 38.2 months, with 3-year actuarial EFS estimates of 74.7%. These impressive results show the value of GTR of ependymoma, and that effective targeting of ependymoma can be achieved by using conformal techniques without an increase in the relapse rate at the margin of the treatment volume. Children treated with CRT had their IQs evaluated before and after radiation, and surprisingly, their IQs were normal and did not significantly change during the study period (there was a trend toward improvement). The same group also published two reports finding that postoperative deficits were not made worse during CRT or improved during CRT.^{102,103} These results suggest that CRT is the preferred modality for radiotherapy in children with localized ependymoma and should not be delayed to allow recovery of postoperative deficits.¹⁹

Repeated irradiation is described by the St. Jude and Toronto groups.^{104,105} The St. Jude group treated 38 patients who had recurrent disease with repeated irradiation. In the St. Jude experience, radiosurgery had poor results, with 4 of 5 children dead of disease within a year of treatment, whereas craniospinal radiation resulted in a 4-year EFS rate of 53%. The Toronto group treated 18 patients who had recurrent ependymoma with repeated irradiation. They found an increase in 3-year OS (from 7 to 81%) and a longer time to progression. They documented 2 of 18 patients who had new endocrine deficits and noticed cognitive decline in the patients.

Radiosurgery has been used to treat several children with ependymoma, with good local control and no excessive neurotoxicity.^{8,106-108} When stereotactic radiosurgery should be used instead of open resection is not clear, but it is probably appropriate in children for whom anesthesia carries a high risk and in children with very small tumors that are in locations with high surgical risks. Currently at St. Jude, children who present with recurrent ependymoma within a previously irradiated field undergo maximal safe surgical resection of the recurrence followed by CRT to the tumor bed. Stereotactic radiosurgery has not proved beneficial in this group of children in our experience.

41.8.2 Chemotherapy

The role of chemotherapy in the treatment of childhood ependymoma is unclear; it does not make up part of the standard care of children with ependymoma. The response rate of ependymoma to single agents is 11%, with fewer than 5% showing complete responses.¹⁰⁹ Of the single-agent chemotherapeutics tried in ependymoma, cisplatin seems to be the most active.¹⁰⁹ In those rare children with ependymoma that responds to chemotherapy, there is no clear increase in survival. Several retrospective reviews have failed to show a benefit for cytotoxic chemotherapy in the treatment of newly diagnosed ependymoma.^{4-7,10,100,110} The CCG-942 randomized controlled trial compared children with ependymoma who received irradiation alone with those who received radiation and chemotherapy;

there was no survival benefit in the arm that received chemotherapy.³ Similarly, the POG-9233 trial did not show an overall survival benefit for infants with ependymoma treated with dose-intensive chemotherapy. The International Society of Paediatric Oncology (SIOP) trial treated 73 children with chemotherapy for 16 to 18 months after maximal resection; the children did not receive radiotherapy. PFS estimates at 2 and 4 years were 33% and 22%, respectively.¹¹¹ These results are clearly worse than those in historical controls treated with radiotherapy. One additional option being investigated is the superselective intra-arterial delivery of chemotherapy via the feeding arteries of recurrent/residual tumor.¹¹² Despite the best efforts of the neuro-oncology community, there is no clear role for current chemotherapy in the upfront treatment of children with localized ependymoma.

Chemotherapy may have a role in the treatment of children with residual tumor after an initial tumor resection. It has been suggested that the administration of chemotherapy between first and second craniotomies made the tumor borders more defined and easier to dissect.²⁶ Chemotherapy may also have a role in the treatment of children who need to delay surgery or radiation treatment because of illness or neurologic complications of the disease or its treatment. There is also benefit when chemotherapy is administered to very young infants with bloody tumors to reduce vascularity.⁹³

One reason that ependymomas have such a poor response rate to chemotherapy may be their expression of the *MDR1* gene, which is known to mediate drug resistance.^{113,114} Future research should include an examination of the effects of chemotherapy while the product of the *MDR1* gene is blocked.¹⁰⁹ Although GTR and CRT are the best treatments currently available for ependymoma, they are unlikely to improve drastically in the future. The development of novel chemotherapeutic strategies, particularly rational therapies based on the biological abnormalities found in the tumor, remains the best hope for future treatments.

Pearls

- Ependymoma is a neurosurgical disease, with local control the most important prognostic factor.
- Failure to obtain a GTR on postoperative imaging should usually prompt consideration of a second resection to improve the likelihood of long-term disease control, because achieving a GTR, compared with anything less, doubles the chances that a child will survive the cancer.
- CRT should be given to all children with localized ependymoma, except for a small minority with classic supratentorial tumors who undergo GTR.
- Although current cytotoxic chemotherapy has a little-proven role in the treatment of ependymoma, future therapeutics based on the biology of the disease offer hope for more effective, less toxic treatments.

42 Brainstem Gliomas

Heather J. McCrea and Mark M. Souweidane

Brainstem tumors exhibit substantial heterogeneity in their clinical attributes, imaging features, anatomical position, and histologic subtype and grade. Accordingly, the clinical behavior of these tumors can be equally variable but is relatively well defined based largely upon the anatomical growth pattern, a feature that parallels magnetic resonance (MR) imaging findings. It is therefore important to categorize a patient's tumor based on this information in order to provide appropriate diagnostic and therapeutic recommendations.

42.1 Epidemiology

Brainstem tumors account for 10 to 20% of all central nervous system tumors in children.¹⁻⁴ Of brainstem gliomas, approximately 80% are diffuse intrinsic pontine gliomas (DIPGs), which carry a very poor prognosis.¹ However, roughly 15 to 20% are low-grade astrocytomas, and these follow a more indolent course. Approximately 150 to 400 children in the United States and 20 to 30 in the United Kingdom are thought to develop brainstem gliomas annually.^{1,3-7} The total incidence of brainstem tumors of all types rose from 0.31 per 100,000 between 1977 and 1981 to 0.67 per 100,000 between 1990 and 1994.⁵ This increase is primarily thought to be secondary to increased detection through the introduction of MR imaging rather than a true increase in the incidence of these tumors. There appears to be equal incidence regardless of gender. The most common age at diagnosis is 5 to 9 years, but cases have been seen in all age groups from infants to adults.⁶

42.2 Classification and Treatment Approaches

The classification of brainstem tumors is typically based on MR imaging.⁸ The overwhelming number of intrinsic brainstem tumors are astrocytic. Peculiarly, the histologic subtype and grade are fairly well predicted based on anatomical position or classification of the tumor. Tumors can be divided according to their location in the midbrain, pons, or medulla,⁸ and Epstein and Farmer suggested dividing tumors into three groups: cervicomedullary, focal medullary, and dorsal exophytic or diffuse anaplastic astrocytomas.⁹ Today, the classification of these tumors encompasses five principal and distinct subgroups: tectal (mesencephalic) tumors, DIPGs, focal tumors, dorsal exophytic tumors, and cervicomedullary tumors. Of course, not every brainstem tumor can be categorized as one of these defined entities, and the pathology may digress from the descriptive term. Because the current categorization scheme is defined by the anatomical features based on imaging, predicting the rare primitive neuroectodermal tumor (PNET) or ganglioglioma can be problematic, if not impossible. Therefore, any clinical or imaging aspects that raise suspicion about the conformity of the diagnosis should serve as an impetus for diagnostic sampling.

42.2.1 Tectal (Mesencephalic) Tumors

Approximately 5% of brainstem tumors are located in the tectal plate.¹⁰ They are most commonly indolent, slow-growing lesions limited to the rostral mesencephalon. Rarely, extension of the tumor into the posterior diencephalon occurs. They create symptoms primarily through the obstruction of cerebrospinal fluid (CSF) flow at the level of the cerebral aqueduct, resulting in symptomatic hydrocephalus.

On imaging, the tectal glioma is characterized by a thickened collicular plate with compression of the cerebral aqueduct. Resulting triventricular hydrocephalus is universally present unless the diagnosis is incidental. Because contrast enhancement is not likely, the mass is most easily seen on FLAIR (fluid-attenuated inversion recovery) and T2-weighted sequences on magnetic resonance (MR) imaging. The typical appearance includes hyperintensity on T2-weighted imaging and hypo- or isointensity on T1-weighted imaging (► Fig. 42.1).¹⁰ Lesions usually have poorly defined margins, although examples of focality have been reported.¹¹ Exophytic growth patterns are infrequent, but infiltrative growth into one or both thalami can occur with some regularity. This lack of exophytic growth into the quadrigeminal cistern helps to distinguish most mesencephalic tumors from tumors originating from the pineal gland. However, for large midbrain tumors and those extending into the pineal region, serum alpha fetoprotein, β -human chorionic gonadotropin, and placental alkaline phosphatase should be measured in order to rule out primary CNS germ cell tumors (discussed in Chapter 39, "Pineal Region Tumors").² The pathology of midbrain tumors, if obtained, is typically low-grade astrocytoma or more rarely ganglioglioma.^{10,12}

Surgical Treatment

The surgical treatment of midbrain tumors is typically restricted to the treatment of hydrocephalus. Given the obstruction to CSF flow at the level of the cerebral aqueduct, the currently preferred method for CSF diversion in these patients is an endoscopic third ventriculostomy (ETV). Patients occasionally require a repeat ETV, but overall, the literature suggests that 80 to 100% of patients undergoing ETV in this scenario remain shunt-free with excellent control of the hydrocephalus.¹³⁻¹⁵ With respect to the tectal tumor, surveillance monitoring with serial MR imaging is generally used, with more frequent imaging (3 to 6 months) shortly after diagnosis and then annually if the mass remains stable.^{2,16} Biopsy of these tumors is reserved for patients who exhibit a rapid neurologic course, unusual imaging features, or progressive radiographic findings. It is not recommended that a routine simultaneous endoscopic tumor biopsy be performed at the time of ETV for patients with typical clinical and imaging findings. For those with tumors that ultimately progress, tissue sampling is recommended. Suitable surgical approaches are determined based upon the degree of ventricular enlargement, tumor growth pattern, and focality of the mass.

(b) Axial T2-weighted MR image and (c) axial FLAIR (fluid-attenuated inversion recovery) MR image for the same patient demonstrating hyperintensity. (d) Axial T1-weighted MR image with gadolinium contrast demonstrating typical lack of contrast enhancement. (e) Sagittal T1-weighted MR image with gadolinium contrast and (f) sagittal T2-weighted MR image.

Nonoperative Management

Patients with midbrain tumors typically do well, and conservative management after the treatment of hydrocephalus is often the most appropriate course. However, approximately 18 to 31% of tumors will eventually require treatment.^{10,17} The size at presentation appears to have a significant correlation with the need for future treatment. A recent study showed that all tumors larger than 10 cm³ at presentation ultimately required treatment, whereas the majority of those smaller than 4 cm³ did not require intervention.¹⁰ However, some patients with tumors in the smallest size subgroup do ultimately require treatment (13.6% in this series), so surveillance is recommended even in these cases of seemingly benign lesions.¹⁰ For patients whose tumors progress, one of a variety of approaches may be employed, such as irradiation, chemotherapy, or subtotal resection with irradiation of residual tumor. Both irradiation and surgery appear to be extremely effective; Pollack et al reported regression or stabilization in patients treated with irradiation, and Ternier et al reported control with surgery and repeated surgery if needed.^{10,17} Ternier et al reported only one death in their cohort of 40 patients.¹⁰

42.2.2 Diffuse Intrinsic Pontine Glioma

DIPG arises from the pons, is infiltrative, and may extend into the midbrain or cerebellar peduncles.¹⁸ Patients who have DIPG typically present with focal neurologic deficits and develop hydrocephalus only as a later sequela. Cranial nerve abnormalities most commonly manifesting as ocular imbalance are commonly

the first sign of these tumors. Other common cranial neuropathies include eye movement abnormalities, diplopia, dysphagia, dysarthria, and facial weakness or sensory loss.² Head tilting to compensate for diplopia may be noticed in children who are too young to describe visual problems. Cerebellar dysfunction is another common presenting sign of these tumors, and limb weakness can result from involvement of corticospinal tracts.^{2,19}

The MR imaging findings of DIPG are consistent with a hypocellular tumor that has more limited blood flow and angiogenesis than high-grade tumors. DIPGs are typically hypointense on T1 imaging and hyperintense on T2 and FLAIR imaging, with indistinct borders (► Fig. 42.2). Enhancement typically makes up only 0 to 25% of the tumor volume.¹⁸ Additional findings may include engulfment of the basilar artery or necrosis, but cysts are uncommon. MR spectroscopy shows a small decrease in *N*-acetylaspartate and an increase in choline, and MR perfusion demonstrates hypoperfusion.¹⁸ Atypical features include prominent enhancement, decreased T2 or FLAIR signal, restricted diffusion, and/or extensive exophytic components.

Although MR imaging is the standard modality for imaging brainstem lesions, advanced imaging modalities are under investigation and may prove useful in the future. A recent study of proton magnetic resonance spectroscopy in children with DIPG suggested that patients with an increased choline to *N*-acetylaspartate (Cho:NAA) ratio (thought to be suggestive of increased cell turnover, cell number, and neuronal damage) have a worse prognosis, and that an increase in this ratio from one time point to another is inversely associated with survival.⁶ This is consistent with studies in adult gliomas, which have shown that an increased Cho:NAA ratio correlates with a higher

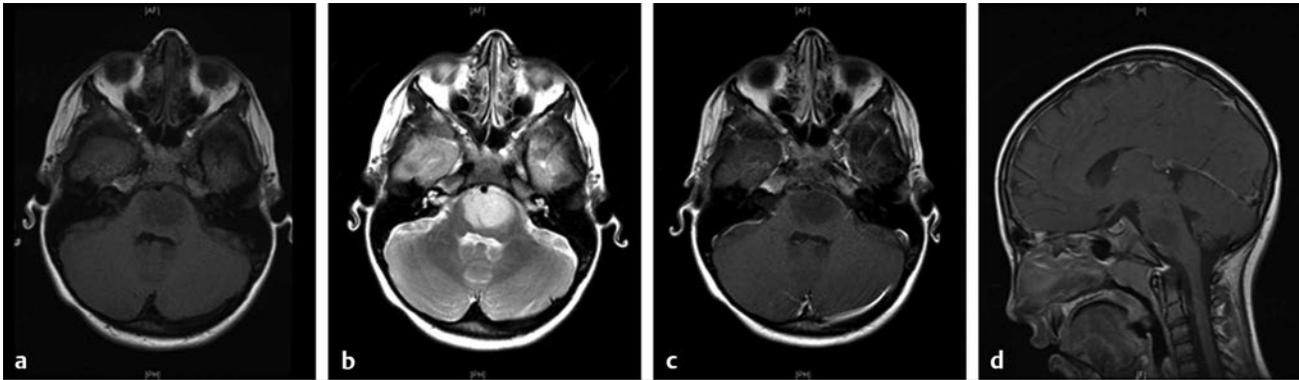

Fig. 42.2 Diffuse intrinsic pontine glioma (DIPG). (a) Axial T1-weighted magnetic resonance (MR) image of a child with DIPG demonstrating classic hypointensity and indistinct margin. (b) Axial T2-weighted MR image of the same patient demonstrating classic hyperintensity. (c) Axial T1-weighted MR image with gadolinium contrast demonstrating lack of enhancement. (d) Sagittal T1-weighted MR image with gadolinium contrast.

histologic grade.⁶ Positron emission tomography (PET) may also be of use in the assessment of DIPG, with two recent studies suggesting a trend toward a shorter length of survival in patients with increased fluorodeoxyglucose (FDG) uptake on PET.^{20,21} PET may also help in guiding stereotactic biopsy sampling because samples taken from areas with FDG uptake showed an equal or higher grade than areas without uptake, and in this small series the diagnostic yield was increased when PET information was used to guide the trajectory.²⁰

MR imaging appears to be very accurate for classifying tumor type in cases with classic findings. In a recent study correlating imaging findings with histology in 44 patients with brainstem tumors, 100% of diffuse nonenhancing brainstem lesions (i.e., cases with imaging features typical of DIPG) were found to be consistent with astrocytoma with predominantly low-grade features (8 low-grade cases and 1 high-grade case). Of the enhancing diffuse lesions (atypical of DIPG), 90% were diffuse brainstem glioma, with a much higher proportion of high-grade samples in these biopsies (14 high-grade and 4 low-grade cases). The tumors of the two patients in whom other pathologies were identified included 1 ependymoma and 1 ganglioglioma.²²

Surgical Treatment

Diffuse tumors are not resectable, and the role of biopsy in DIPG remains limited to tissue sampling for molecular therapeutic strategies or investigational purposes. Before the routine use of MR imaging, biopsies were performed to confirm diagnosis and provide information regarding prognosis. Since the advent of MR imaging, DIPG can often be diagnosed without biopsy. Albright et al argued that biopsies were frequently not indicated in children with brainstem lesions because the lesions could be diagnosed and treated solely on the basis of MR imaging without subjecting the children to the risk of biopsy.²³ An important aspect of diagnosis today involves differentiating between “classic” DIPG and “atypical” DIPG; “classic” DIPG is typically diagnosed solely on imaging, whereas biopsy may play a role in “atypical” DIPG in order to rule out alternate diagnoses. Additionally, as more molecularly specific treatments are developed, the likelihood that biopsy may alter treatment and the need for biopsies for this reason should increase. The information gained

through the biopsy and characterization of these tumors could prove critical to a better understanding and treatment of these neoplasms. Although many neurosurgeons would not biopsy a “typical” DIPG, considerable variability exists between pediatric neurosurgeons as to whether an individual case is typical or atypical and whether or not they would consider biopsy of a lesion.²⁴ A range of biopsy approaches are used depending on tumor characteristics and surgeon preference, including stereotactic suboccipital–transcerebellar biopsy, stereotactic supratentorial–prefrontal biopsy, and open biopsy.^{24,25} Most historical series investigating risk of biopsy were done with computed tomography (CT)–guided imaging. They suggest a 0 to 4% mortality rate, a 0 to 4% permanent morbidity rate, and a 0 to 28% transient morbidity rate.^{26–32} The most recent study suggests 0% mortality, 0% permanent morbidity, and 8% transient morbidity.³¹ Today, MR imaging–guided biopsy has replaced CT-guided biopsy. With MR imaging–guided stereotactic biopsy, the risk for mortality and morbidity was recently estimated to be between 0 and 6%.¹⁸ Of note, parents of children with DIPG seem to be willing to allow biopsy, with a recent study showing that 24% of parents would consent to biopsy for the sole benefit of future treatment development without any direct benefit to their child and that 55% would consider biopsy if there were only a slight chance of benefit.¹⁸ Thus, given the low morbidity of biopsy with current stereotactically guided techniques, biopsy may increasingly be indicated as part of clinical trials and as an aid to treating patients with specific molecular therapeutics. Additionally, biopsy may be indicated in diffuse lesions with atypical features in order to rule out other types of brainstem lesions that may be more amenable to resection or other therapy.

Radiation and Chemotherapy

Standard conventional radiation therapy consisting of daily fractions given 5 days a week for up to 6 weeks is the standard of care for DIPG, with a total dose of approximately 54 Gy.^{1,2,16,18} Most literature suggests the prolongation of progression-free survival but not overall survival with radiation, although a recent study suggested a small survival benefit in patients treated with radiation.^{7,33,34} Hyperfractionated and hypofractionated regimens have not shown any significant benefit in overall

survival when compared with standard conventional radiotherapy.^{1,7,18} The risk for brainstem injury appears to increase at doses greater than 64 Gy.¹⁸ Overall, radiation has an 85% clinical response rate but only a 50% radiologic response rate.¹ The clinical and radiologic responses do not directly correlate, and the relevance of the radiologic response is not clear.¹ Additionally, for most patients, radiation provides only a transient improvement or stabilization of symptoms, with progression of disease about 8 to 9 months after diagnosis.^{16,18} Once tumors progress, there is a tendency for rapid deterioration, with the median time between progression and death ranging from 1 to 4.5 months.¹ A recent study also suggested that radiation had similar effectiveness when delayed by upfront chemotherapy.³⁵

Most studies of chemotherapy for brainstem lesions have focused on DIPG, yet chemotherapy has not been shown to offer a clear survival benefit when used alone or in conjunction with radiotherapy in these tumors.¹ Assessment of chemotherapy results has also been limited by varying patient populations and criteria for response in the different trials, making a comparison of results difficult.¹ One study suggested a possible benefit of chemotherapy in patients in the HIT-GBM database (primarily a German database). The study found that patients treated with chemotherapy showed an increased median survival compared with those treated without chemotherapy, yet most patients who did not receive chemotherapy also did not receive radiation. When only patients treated with irradiation were included, patients treated with chemotherapy and radiation did have a longer survival than those treated with radiation alone.³⁴ However, this study included patients treated with several different chemotherapy regimens, and it is not clear whether the populations of patients who received chemotherapy and who did not are comparable. Another study, which demonstrated the longest published median survival of 17 months, suggested that preradiation chemotherapy may extend survival.³⁵ In this study, BCNU (bischloroethyl-nitrosourea), cisplatin, and in some patients tamoxifen were alternated with two courses of high-dose methotrexate before radiation. Patients then received standard radiation with concurrent hydroxyurea. However, the cost of chemotherapy was high, with significantly longer hospital stays and multiple serious infections.³⁵ Additionally, the patient cohort had a mean duration of symptoms of approximately 2 months before the initiation of therapy, and a longer prodrome has been associated with better survival. Further clinical trials with varying chemotherapy regimens are currently under way.

Future directions include chemotherapeutic agents or therapy with specific molecular targets and the stratification of chemotherapy based on the presence of these targets in a patient's tumor. Two recent Phase I studies of imatinib used this strategy. Imatinib (Gleevec/Glivec; Novartis, East Hanover, NJ) inhibits PDGFR, ABL, and c-KIT tyrosine kinases by inhibiting the adenosine triphosphate (ATP)-binding site. These studies looked at KIT, PDGFRA, and PDGFRB expression in the tumors of patients who were then treated with imatinib.^{36,37} Although neither study demonstrated a clear response of tumor to drug, both had individual patients with stable disease, and they provide an important blueprint for testing chemotherapeutic agents in conjunction with assessing the presence of their molecular target. A previous Phase I trial of imatinib without molecular stratification also had two patients who appeared to respond, but

the majority of patients did not exhibit a response.³⁸ The molecular status of these two patients is unknown. Of note, imatinib has poor penetration of the blood-brain barrier; the second-generation tyrosine kinase inhibitor dasatinib (Sprycel; Bristol-Myers Squibb, New York, NY) shows much better permeability.³⁷ Another molecularly targeted therapy, gefitinib (ZD1839, Iressa; AstraZeneca, Wilmington, DE), an EGFR tyrosine kinase inhibitor, was recently tested in a Phase II study, and patients treated with this agent appeared to show slightly more positive survival and progression-free survival rates than those of historical controls.³⁹ Given the variability of brainstem tumors, it is impossible to determine whether the children in this study are similarly representative of those in historical studies. Thus, the effect could be either over- or underestimated. However, these patients did not undergo biopsy, so EGFR expression in the tumors treated is not known, raising the possibility that the results might improve significantly if only patients with EGFR expression were treated. EGFR can also be targeted via monoclonal antibody, and nimotuzumab, a humanized anti-EGFR monoclonal antibody, appears promising in preliminary clinical studies.⁴⁰ Future trials should focus both on molecular stratification and efficient delivery of chemotherapeutic agents in order to achieve the best results. Additionally, combinations of molecularly targeted chemotherapies may be more beneficial than treatment with individual agents.

Therapeutic Advances (Molecular Characterization, Vaccine Therapy, Convection-Enhanced Delivery)

Understanding the biology of DIPG and other brainstem tumors is an important step in developing more effective treatments. Most research on brainstem tumors has been focused on DIPG, given its grim prognosis; however, the study of DIPG has been limited by a lack of tissue due to the difficulty of operating in this area. Brainstem biopsies were first suggested in the late 1970s and 1980s, but by the 1990s, biopsies were discouraged in typical cases of the disease. Consequently, tissue samples have primarily been restricted to autopsy samples. However, recently some progress has been made in defining the molecular characteristics of DIPG. This is critical for deriving appropriate chemotherapeutic strategies. Previously tried drugs have primarily been those used for adult glioblastoma, but DIPG appears to have distinct biological differences from adult glioblastoma multiforme and even from pediatric supratentorial high-grade glioma,⁴¹⁻⁴³ with the exception of some cases of pediatric midline/thalamic supratentorial high-grade glioma, which may have some similarities.⁴³

Zarghooni et al undertook whole-genome profiling of 11 patient samples of DIPG. Their results may not be fully representative because these were primarily autopsy specimens. Nonetheless, some important molecular characteristics of DIPG began to emerge. In their study, 50% of DIPG samples showed gain of *PDGFA* or *PDGFRA*. Additionally, all samples showed expression of PDGFR- α and downstream target phospho-mTOR (mammalian target of rapamycin).⁴¹ Becher et al similarly found a high rate of expression of PDGFR- α in high-grade brainstem glioma samples, with 87.5% of surgical samples and 50% of autopsy samples showing immunopositivity (overall rate, 67%).⁴⁴ Paugh et al found gains of receptor tyrosine kinases in 56% of their

DIPG samples and reported that gains of *PDGFRA* were seen in 30%. They found overexpression of *PDGFRA* in tumors with amplification and even in a subset of tumors without amplification.⁴² These results suggest that the PDGF pathway may play an important role in DIPG. This is further supported by the induction of brainstem gliomas in mice through overexpression of *PDGF* in the posterior fossa, and the establishment of a PDGF-induced brainstem glioma mouse model that recapitulates many of the features of brainstem glioma.⁴⁴ Other receptor tyrosine kinases seen to have recurrent gains in DIPG (although with a lower frequency than *PDGFRA*) are *MET*, *IGF1R*, *ERBB4*, and *EGFR*.⁴² Of note, overexpression of *IGF1R*, *PDGFRA*, and *EGFR* has also been seen in cases without amplification of the genes.^{41,42} The role of the *EGFR* pathway is less clear, with one study suggesting that it is less frequently involved in DIPG than in adult supratentorial glioblastoma multiforme, and another study suggesting that *ERBB1* is amplified and overexpressed in high-grade DIPG samples.^{41,45} Additionally, another recent series with a small number of samples found that 40% of samples demonstrated expression of epidermal growth factor receptor variant III (*EGFRvIII*), the most common variant of *EGFR*, which is expressed in many tumor samples but rarely in normal tissue.⁴⁶ This finding has been used as the basis for a Phase I trial of an *EGFRvIII* peptide vaccine (a vaccine previously trialed in adult patients with glioblastoma multiforme) after conventional radiotherapy in patients with DIPG.⁴⁶

Genomic analysis suggests that the transcription factors and genes associated with developmental processes are most significantly differentially expressed in DIPG versus cerebral pediatric high-grade glioma. In particular, members of the *HOX* family, critical genes for correct development, including *HOXA3*, *HOXA2*, *HOXD3*, *HOXB2*, and *HOXD4*, show significantly higher expression in DIPG.⁴² Loss of heterozygosity analysis has suggested that mutations in DNA repair pathways may also play an important role in DIPG, and poly (ADP-ribose) polymerase-1 (*PARP1*), a DNA repair gene that is critical for tumor survival in patients with compromised DNA repair ability, was gained in several tumor samples.⁴¹ *PARP* protein was seen to be expressed in additional samples, and *PARP* inhibition could be a potential therapeutic target.⁴¹

One study looking at genetic alterations found that loss of 11p, 17p, 14q, 18p, and 22q was more frequent in DIPG than in pediatric supratentorial high-grade gliomas. Gains of 17q and 10p were unique to DIPG, whereas gains of 1q and 9q were common to DIPG and pediatric high-grade supratentorial gliomas in other locations.⁴¹ Another study with a larger number of samples found DIPG had more frequent gains of chromosomes 2q, 8q, and 9q and losses of 16q, 17p, and 20p than non-brainstem glioblastoma. Chromosome 7 gain and 10q loss were comparable in DIPG and non-brainstem pediatric glioblastoma but less frequent than in adult glioblastoma multiforme, and gain of 1q was similar in DIPG and pediatric glioblastoma multiforme but more frequent in both than in adult glioblastoma multiforme. Loss of 13q and 14q was similar in glioblastoma multiforme in all ages and locations.⁴² A third study showed that loss of 17p and 14q was more common in DIPG than in pediatric high-grade glioma, and gain of 1q was seen at approximately similar rates in both DIPG and pediatric high-grade glioma.⁴⁷ These studies share the findings that loss of 17p is more common in DIPG than in other gliomas and that gain of 1q is

common to both pediatric DIPG and supratentorial glioblastoma multiforme. Of note, 17p is the location of the *TP53* tumor suppressor gene.

Puget et al recently published their results analyzing DNA and RNA from 32 and 23 patients, respectively, with biopsies taken at time of initial diagnosis, the largest sample size to date.⁴³ They suggest that DIPG can be subdivided into two groups that, although different from adult glioblastoma multiforme, have similarities to the proneural and mesenchymal variants of glioblastoma multiforme, respectively. The first group is characterized by overexpression of oligodendroglial markers and strong expression of *Olig2* by immunohistochemistry. The gene expression profile of this group was significantly enriched for *PDGFRA* and the genes associated with this receptor. Additional receptor tyrosine kinases were sometimes also amplified. The survival of this group was significantly worse than that of the second group; 70% of children died before the median overall survival of 10.6 months, whereas 10% of the second group died before this median survival. When samples were compared based on histology alone (allowing the inclusion of 55 samples), patients with oligodendroglial features had a 7.73-month overall survival, compared with a 12.37-month survival for those who had primarily astrocytic features. DIPG in the patients in group 2 was characterized by the upregulation of mesenchymal transition genes, including master epithelial-mesenchymal transition regulators *SNAI1* and *SNAI2/Slug* genes, overexpression of proangiogenic genes, endothelial proliferation, and activation of the *HIF1A* pathway. Group 2 tumors had a higher expression of *STAT3*, a gene whose elimination promotes neurogenesis and inhibits astrogenesis, and these tumors also appeared to be more similar to fetal neural stem cells.⁴³ Additionally, numerous homeobox genes and genes in the sonic hedgehog pathway were found to be overexpressed in brainstem gliomas as opposed to supratentorial high-grade gliomas, and *LHX2* and *IRX2*, two genes that have been described to be preferentially overexpressed in posterior fossa pilocytic astrocytoma and ependymoma compared with supratentorial tumors of the same histology, were also seen to be overexpressed in DIPG compared with supratentorial high-grade glioma. This suggests that there may be gene expression profiles in glial tumors related to the location of origin regardless of histologic diagnosis,⁴³ an idea first proposed for ependymoma and pilocytic astrocytoma. Recently, Monje et al suggested that a nestin + /vimentin + /*Olig2* + cell population in the ventral pons may be the cell of origin of DIPG and that a similar cell population in mice was increased upon upregulation of the sonic hedgehog pathway.⁴⁸

The most recent avenue of genetic research involves a focus on histone H3 mutations. Histone lysine methylation is thought to play an important role in regulating gene expression and chromatin function, and H3.3 is the major histone associated with chromatin during brain development. Two recent studies demonstrated that more than 70% of DIPGs had a lysine-to-methionine mutation on histone H3.3 (K27M-H3.3) or the related H3.1.^{49,50} Additionally, it was found that patients with the K27M-H3.3 mutation have a significantly worse prognosis than patients with wild-type H3.3, and that *PDGFRA* gain or amplification is seen only in patients with this mutation, suggesting that histone mutation is an early event in the development of DIPG.⁵⁰

An additional avenue of research is that of improving therapeutic delivery. The effectiveness of the systemic delivery of chemotherapy for brain tumors is significantly inhibited by the blood–brain barrier. Even a drug that is effective in the laboratory against glioma may not achieve high enough concentrations in the brainstem to have an effect. Thus, research addressing improved delivery to the brainstem is critical, in addition to research investigating improved chemotherapeutic agents. One such delivery method is interstitial infusion, or convection-enhanced delivery (CED). In this method, an agent, such as an antibody- or tumor-targeted toxin, may be infused through a small cannula directly inserted into a tumor in order to deliver the agent throughout the tumor. Brainstem tumors, with their focal location and poor prognosis, seem an ideal target for this therapy.⁵¹ Studies in rats and primates have suggested that agents can safely be delivered to the brainstem via CED.^{52–54} Additionally, a radiation-induced recurrent glioblastoma in the brainstem of a patient in Japan was found to regress after CED of nimustine hydrochloride.⁵⁵ Currently, clinical trials are under way to determine the safety and efficacy of delivering specific agents via CED in pediatric patients with DIPG.

Overall, a new understanding of the biology of brainstem tumors will help in the development of improved therapeutics, and stratification based on tumor biology may help identify subsets of patients who might benefit from currently available therapies. The combination of research into new therapeutics and new delivery methods offers the best hope of an improved treatment strategy for these currently challenging tumors.

42.2.3 Focal Brainstem Tumors

Focal brainstem tumors may be located anywhere within the brainstem but are not usually located within the ventral pons. Focal tumors have well-defined margins typically best appreciated on T2 or FLAIR imaging and occupy less than 50% of the axial diameter of the brainstem.²² They are typically hypointense on T1 imaging and hyperintense on T2 imaging, and they have variable contrast uptake. They may be solid or cystic; however, the area of tumor identified on T1 imaging is usually equivalent to the area identified on T2 imaging.⁵⁶ Focal tumors may present with headache, diplopia, swallowing difficulties, long tract signs, or other cerebellar or cranial nerve dysfunction depending on their location. Symptom duration is typically longer for low-grade tumors and shorter for higher-grade tumors. Focal brainstem gliomas are typically pilocytic astrocytomas or other low-grade gliomas.^{22,57} Less frequently, they may be gangliogliomas or high-grade gliomas.^{22,57}

Surgical Treatment

An attempt at surgical resection should be considered for tumors that are clearly focal on imaging. The surgical approach must be tailored to the location of tumor. A study of 34 patients with focal brainstem lesions undergoing surgery demonstrated 0% postoperative mortality, 15% morbidity, and symptom improvement in 65% of patients.⁵⁶ The selection of patients with clearly focal tumors and surgeon experience are both key to minimizing surgical morbidity. Neurophysiologic monitoring is also helpful in facilitating resection. For patients with tumors

that are not clearly characterized as focal or diffuse through MR imaging, one strategy is to perform stereotactic biopsy and subsequently consider resection if the pathology demonstrates pilocytic astrocytoma, other low-grade astrocytoma, or ganglioglioma.

Radiation and Chemotherapy

Radiation or chemotherapy may be indicated for patients with unresectable lesions or for those with residual tumor after subtotal resection. Gamma knife radiosurgery has also been used to treat focal lesions; one study of 20 patients demonstrated an 84% progression-free survival rate at 5 years.⁵⁸ However, the mean duration until tumor shrinkage was 14.8 months. Tumor response was correlated with higher Karnofsky performance score, higher peripheral dose, smaller tumor volume, and longer symptom duration before radiation on univariate analysis and with Karnofsky performance score alone on multivariate analysis.⁵⁸

42.2.4 Dorsal Exophytic Tumors

Dorsal exophytic tumors are frequently found within the medulla, although they may also arise from the pons and pontomedullary junction. They protrude from the brainstem dorsally into the fourth ventricle. On MR imaging, they typically are hypo- or isointense on T1 and hyperintense on T2, and they show contrast enhancement (► Fig. 42.3).¹² Patients frequently present with signs and symptoms attributable to hydrocephalus, such as failure to thrive or headache and vomiting, and are more likely to have a longer symptom duration before diagnosis than patients with other types of brainstem tumors.¹² Papilledema, nystagmus, and cranial nerve dysfunction are also common findings. Long tract signs are not typically seen. Histology typically demonstrates low-grade (World Health Organization [WHO] grade I or II) astrocytomas or gangliogliomas.^{2,12}

Surgical Treatment

Attempted resection is indicated for dorsal exophytic tumors, and the prognosis is thus significantly better than that for diffuse or focal tumors. These tumors are typically approached through a midline suboccipital craniotomy. The goal is to debulk the exophytic component; however, a gross total resection is often precluded by an indistinct tumor–brainstem interface on the anterior aspect of the tumor (► Fig. 42.3e). Ultrasonic aspiration facilitates debulking. In addition, neuromonitoring is a critical tool in order to allow a safer resection. Neuromonitoring typically includes motor, sensory, and brainstem evoked potentials. Stimulation for cranial nerves allows the differentiation between tumor and brainstem nuclei and helps determine which tissue may safely be removed during surgery. In addition to resection, some patients with dorsal exophytic tumors require surgical intervention to treat resulting hydrocephalus. Because residual tumor is frequently left, patients may require repeated debulking surgery at the time of regrowth of the tumor. Repeated surgery appears to be an effective option for controlling regrowth, and tumors appear to be of similar histology upon regrowth.⁵⁹

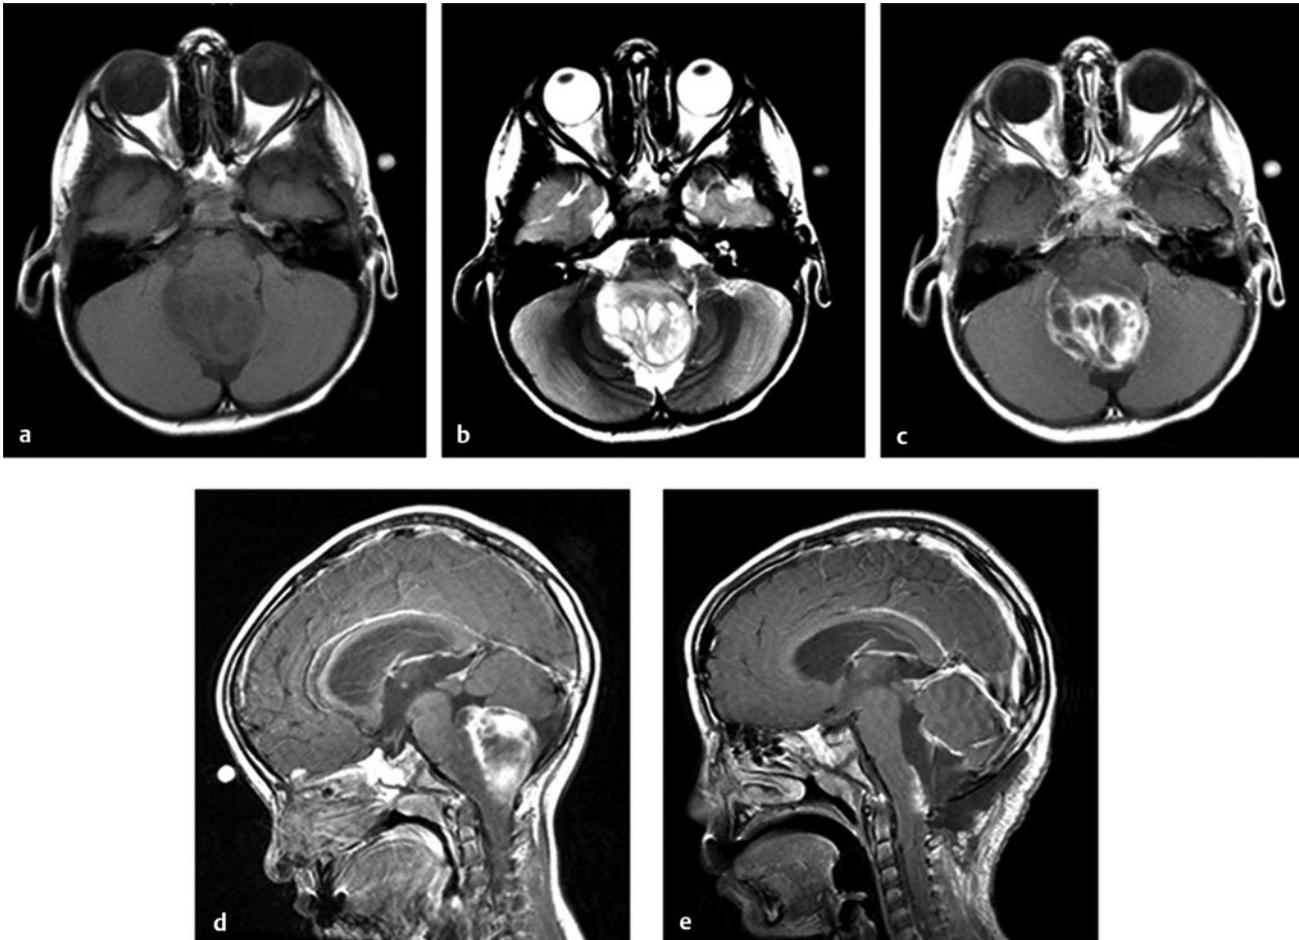

Fig. 42.3 Dorsal exophytic brainstem tumor. (a) Axial T1-weighted magnetic resonance (MR) image of a child with a dorsal exophytic brainstem tumor demonstrating dorsal extension of the tumor. (b) Axial T2-weighted MR image of the same patient. (c) Axial and (d) sagittal T1-weighted MR images with gadolinium contrast demonstrating contrast enhancement, as is typical of this type of tumor. (e) Sagittal T1-weighted MR image with gadolinium contrast of the same patient after resection. Most of the exophytic tumor could be resected. However, these tumors typically have a poorly demarcated interface with the brainstem, so that a small amount of tumor must be left to prevent injury to the brainstem. Note the area of contrast enhancement representing residual tumor on the dorsal surface of the brainstem.

Radiation

Although surgery is the treatment of choice, focused radiation may be used for residual disease in cases of subtotal resection.

42.2.5 Cervicomedullary Tumors

Cervicomedullary tumors often appear similar to upper cervical cord tumors, with behavior more similar to that of spinal cord astrocytomas than that of brainstem gliomas. In these patients, the tumor appears to arise from the cervical cord, with rostral growth limited by the medullary decussation. Margins in these tumors are typically more distinct, with symptoms caused by compression of brainstem fibers rather than infiltration. However, other cervicomedullary tumors behave more like infiltrating tumors of the medulla with caudal extension into the spinal cord. These tumors are more difficult to treat because they have much less distinct margins.⁶⁰ Children with both types of cervicomedullary tumors typically present with bulbar symptoms, focal neurologic deficits of the lower cranial nerves, or long tract signs.

The pathology of cervicomedullary tumors is frequently low-grade glioma but can also be ganglioglioma, anaplastic astrocytoma, or ependymoma.⁹

Surgical Treatment

Cervicomedullary tumors are typically approached through a midline suboccipital craniotomy with cervical laminectomy as needed for cervical exposure. For tumors with distinct margins, complete resection may be possible. However, frequently biopsy or subtotal resection may be more appropriate given their infiltrative (WHO grade II) nature. Neuromonitoring, such as that described above, is typically used to aid resection.

Radiation and Chemotherapy

Radiation or chemotherapy is used in patients who undergo subtotal resection or in whom resection is not possible. The timing of adjuvant therapy and choice of modality depend on the treating oncologist and age of the child. Chemotherapy and radiation may also lead to an increased definition of the

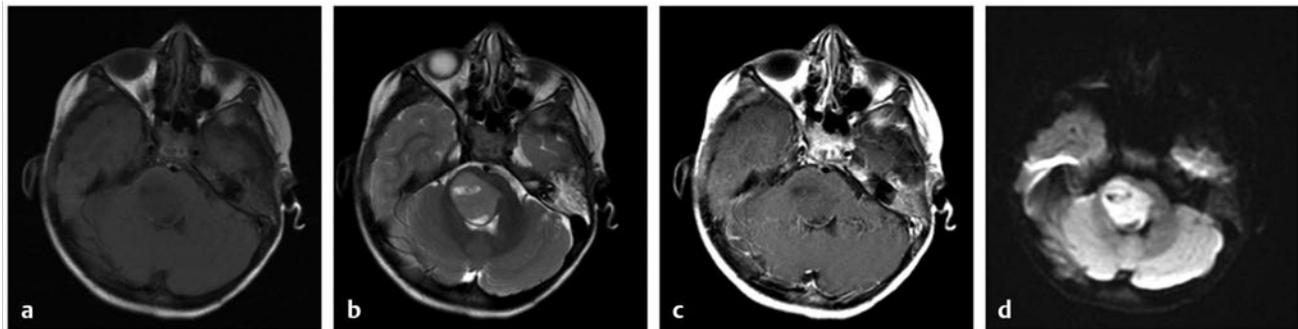

Fig. 42.4 Primitive neuroectodermal tumor (PNET) of the brainstem. (a) Axial T1-weighted magnetic resonance (MR) image of a child with histologically confirmed PNET. (b) Axial T2-weighted MR image of the same patient. (c) Axial T1-weighted MR image with gadolinium contrast. Unlike PNETs in other locations, PNETs in the brainstem typically do not demonstrate contrast enhancement. (d) Axial diffusion-weighted MR image demonstrating diffusion restriction. This finding is typical for PNETs and may help discriminate them from other types of lesions in this area.

brainstem–tumor interface and thus facilitate surgery after adjuvant therapy.⁶⁰

42.2.6 Additional Considerations: Primitive Neuroectodermal Tumors

PNETs may rarely be found in the brainstem. They typically appear as well-circumscribed focal pontine tumors with hypointensity on T1 imaging and hyperintensity on T2 imaging (► Fig. 42.4).⁶¹ Unlike PNETs in other locations, contrast enhancement is usually absent in brainstem PNETs. They often show leptomeningeal spread, and an exophytic appearance is common although variable in degree. Hydrocephalus is also typically present in children with PNETs at the time of diagnosis. The median age of this subpopulation of patients with brainstem tumors appears to be younger than that of typical patients with DIPGs; the average age of patients with brainstem PNETs was 2.7 years in one series.⁶¹ Patients with the appearance of PNETs on MR imaging should undergo biopsy to confirm the diagnosis and resection if possible. Spinal imaging should be obtained in patients with PNETs to determine the extent of leptomeningeal spread, and radiation to the entire craniocervical axis should be considered.

42.3 Prognosis

The prognosis for children with DIPG is extremely poor; the prognosis for children with other subtypes of brainstem tumors is significantly better. In most studies, the survival rate for DIPG is less than 10% at 2 years, with a median survival time of less than 1 year.^{1,16,19,34} In contrast, other brainstem tumors that may be amenable to surgery have a much better prognosis. Sandri et al described an 87.4% rate of 4-year survival and a 58.8% rate of 4-year disease-free survival for nondiffuse tumors, with the most important prognostic factor being extent of resection.¹⁶ Fried et al similarly described a very favorable outcome for brainstem low-grade tumors (a category that includes low-grade tumors of multiple subtypes, described above). In their study, patients with brainstem low-grade tumors had a 5-year progression-free survival of $57\% \pm 3\%$ and an overall survival of $89\% \pm 5\%$.⁶² Fisher et al noted a significant difference in survival based on pathology, with a $95\% \pm 5\%$ -year survival for pilocytic

astrocytomas versus a $23\% \pm 11\%$ 1-year overall survival for fibrillary astrocytomas.⁵⁷

Studies have shown that age younger than 2 years, the presence of cranial nerve palsies (particularly abducens palsy), long tract signs on presentation, a pontine location, encasement of the basilar artery, and a shorter duration of symptoms before diagnosis predict a poor outcome.^{19,57} Patients with neurofibromatosis, an older age, and a longer duration of symptoms before diagnosis are thought to have a more favorable outcome.^{16,19}

Pearls

- Brainstem gliomas are a diverse group of tumors with widely divergent treatment strategies and prognoses, and the likelihood of high-grade pathology and a poor prognosis is very well predicted by location, appearance on MR imaging, and symptoms.
- DIPG is currently primarily treated with radiation; there is little role for surgery.
- Given the poor prognosis of patients with DIPGs, much work is currently being directed at understanding the biology of these tumors and producing better treatment options.
- Tectal, focal, dorsal exophytic, and cervicomedullary tumors are typically low-grade and may be amenable to resection. In many cases, patients have a reasonably good prognosis.

43 Cerebellar Astrocytomas

Pierpaolo Peruzzi, Daniel R. Boué, and Corey Raffel

Except in infants and very young children (younger than 1 year), the posterior fossa is the most common site of occurrence for pediatric primary brain tumors.¹ Of the tumors occurring in this location, medulloblastoma is the most common, accounting for 35 to 50% of cases and presenting mainly in the first decade of life,^{2,3} followed by cerebellar astrocytomas, which can develop throughout childhood and into early adulthood.^{4,5} Historically associated with a favorable outcome, individual cerebellar astrocytomas in reality can display different behaviors, depending mainly on the presence or absence of invasion, extent of surgical resection, and histologic grade. An understanding of the natural history of the disease, as well as the available therapeutic options, is necessary to achieve the best outcome in each case.

43.1 Epidemiology

Cerebellar astrocytomas occur most often in the pediatric population, with 70 to 80% of cases developing in children.^{6,7} They account for 10 to 20% of all pediatric brain tumors^{2,7} and up to 25 to 35% of posterior fossa tumors in children,^{6,8} with an incidence of 0.3 to 0.4 cases per 100,000 children per year.⁸ The mean age at diagnosis is 6 to 7 years^{7,9,10} when patients younger than 18 years are considered, and it is 17 to 18 years when adult cases are taken into account.⁷ Only 3% of cases have been reported in children younger than 1 year.¹¹ Whereas medulloblastoma more frequently affects males, cerebellar astrocytomas show no evidence of a gender predilection.^{5,7,9,10} Historically, pilocytic astrocytoma has been reported as the most frequently occurring tumor, accounting for 70 to 80% of cases, followed by low-grade diffuse astrocytoma (10 to 15%) and higher-grade tumors, such as grade III anaplastic astrocytoma and grade IV glioblastoma multiforme (5%).^{6,12,13} However, if the recently described new entities, such as pilomyxoid astrocytoma and “diffuse” pilocytic astrocytoma (see below), are taken into account, up to 95% of all cerebellar astrocytomas consist of pilocytic and pilomyxoid variants, whereas the remaining 5% consist of diffuse astrocytomas of both low and high grades.¹⁴ The cerebellum is the most common location for pilocytic astrocytoma in children,¹⁵ except in patients affected by neurofibromatosis type 1 (NF-1), in whom cerebellar involvement occurs in fewer than 1% of cases.¹⁶

43.2 Pathology

43.2.1 Gross Appearance

Pilocytic Astrocytomas

Pilocytic astrocytomas (PAs) are very common World Health Organization (WHO) grade I tumors. They grow slowly and have a relatively low propensity for parenchymal infiltration. Often, cerebellar PAs invade the subarachnoid space, but this is not associated with an increased risk for cerebrospinal fluid (CSF) spread or a worse prognosis.¹⁷ Distant leptomeningeal dissemination has been occasionally described and may be (although not

always) associated with a worse prognosis, as long-term survival occurs even without ancillary therapy.^{14,18–21} Thus, CSF dissemination may indicate, for example, simple chance fragmentation and dispersal of tumor already present in the subarachnoid space. PAs usually appear gray to tan–pink and may have pronounced vascularity.¹⁷ Tumor consistency varies from very soft and gelatinous to firm and rubbery (rarely, rock-hard). Lesions in the cerebellar hemispheres often show one or more macrocysts^{10,11} filled with proteinaceous fluid and delimited by a cyst wall that can be either neoplastic or formed by reactive gliosis.^{7,10,22} Macrocysts may occur adjacent to tumor or within tumor. The tumor often appears as a solid mass (“mural nodule”) in the cyst wall. Tumors of the vermis or fourth ventricle are usually less macrocystic.¹⁰ Some PAs appearing to “arise within” the fourth ventricle are actually dorsal exophytic growths from the brainstem that enter the fourth ventricle through the outflow foramina. Calcification occurs occasionally. Hemorrhage also occurs occasionally, and evidence of prior hemorrhage is the presence of perivascular hemosiderin pigment. In a rare case, acute hemorrhage may occur into a macrocyst, causing sudden decompensation with increasing mass effect and intracranial pressure (ICP), edema, herniation, and death.

Pilomyxoid Astrocytomas

Pilomyxoid astrocytomas (PMAs) were characterized in 1999.²³ This tumor was included in the 2007 WHO classification as an independent grade II entity, particularly because of its tendency to more aggressive behavior compared with PA.¹⁴ PMAs are most often seen in the first 2 to 3 years of life and occur mostly in the midline, especially in the region of the optic chiasm, hypothalamus, and third ventricle; in this midline supratentorial region, PMAs may occur in older children, but cerebellar PMAs are generally limited to those younger than 2 to 3 years old. Currently, PMA is believed to represent a more aggressive “variant” of PA, with a greater tendency to local recurrence and CSF dissemination versus PA. This appears especially true of PMAs that arise in the supratentorial midline.^{14,23} Progression-free survival (PFS) is shorter for PMA than for PA, and “death from disease” is more frequent with PMA. Grossly, PMAs are well circumscribed, solid (a small fraction may have a usually minor cystic component), pale tan–pink, soft, and gelatinous. They may also be partly very soft, pale yellow, and necrotic (a small fraction, but more of them than of PAs).

Diffuse Fibrillary Astrocytomas

Diffuse fibrillary astrocytomas (DFAs) are relatively infrequent WHO grade II, grade III (anaplastic astrocytoma), or grade IV (glioblastoma, glioblastoma multiforme) tumors in the cerebellum. They appear as gray–tan–red, ill-defined, infiltrative lesions, with a consistency ranging from firm to gelatinous. These tumors may display microcystic degeneration, but they usually lack the frank macrocystic appearance of many PAs. Glioblastoma multiforme (GBM) characteristically has central necrosis and may show gross thrombosis of associated larger vessels.

43.2.2 Microscopic Appearance

Pilocytic Astrocytomas

The most classic feature of PAs (► Fig. 43.1) is the “biphasic pattern.” This is characterized by dense pink–red fibrillary regions composed of many spindle-shaped bipolar (piloid) astrocytes with elongated nuclei and very long and thin hairlike processes extending from both tips of tumor cells. These regions alternate with intervening looser areas that represent microcystic and often mucinous degeneration of the tumor (with cellular elements composed predominantly of multipolar rather than bipolar cells, cells resembling “protoplasmic” astrocytes, or even oligodendrogloma-like cells with generally more round to oval nuclei).

Other forms of degenerative change seen in PA include increased numbers of hyalinized (thickened and sclerotic, or scarred) blood vessels, occasionally associated with downstream foci of bland ischemic-type tumor necrosis, possibly related to occlusive events occurring within these abnormal vessels, and often marked yet benign nuclear atypia or pleomorphism; both hyalinized vessels and “degenerative”-type nuclear atypia are common in PA. The latter may appear worrisome (resembling anaplasia to the inexperienced), but these markedly atypical nuclei express no proliferation markers, show no mitotic activity, and occur in a background of otherwise typical features of PA. In addition to increased nuclear atypia, foci of necrosis, and extension into the subarachnoid space, other features that may appear worrisome to the less experienced eye include rare scattered mitotic figures, glomeruloid-type vascular proliferation (usually capillary-size vessels with multiple lumina and often only simple hypertrophic endothelium, but occasionally intraluminal hyperplasia or

multilayering of endothelial-type cells, the latter tending to occur adjacent to macrocysts), and sometimes relatively increased cellularity. None of these aforementioned features have any prognostic significance in PA.^{14,24} Subarachnoid spread of PA is evidenced by a micro-multinodular pattern of growth, with variably thin fibrous septae present between small tumor nodules.

Other often helpful diagnostic features, which alone are *neither necessary nor* sufficient for the diagnosis of PA, include Rosenthal fibers (dense, glassy, hyaline pink–red intracytoplasmic inclusions, seen as corkscrew-shape structures in longitudinal sections or as discrete round to ovoid bodies in cross sections and mainly concentrated in the denser pink fibrillary areas of the tumor) and eosinophilic granular bodies, also intracytoplasmic and round but granular pink–red, raspberry-like protein aggregates, typically better seen in looser microcystic/mucinous foci.^{25,26}

Rosenthal fibers are also seen in reactive (“piloid”) gliosis and thus are not always a sign of neoplasia. In piloid gliosis, the number of Rosenthal fibers present usually is greater than the number of nuclei seen, and microcystic change is also not generally present.

Pilomyxoid Astrocytomas.

The microscopic appearance of PMAs (► Fig. 43.2) is characterized by the following: a markedly predominant to solely (i.e., monophasic) “loose” microcystic/mucinous or myxoid background pattern, without any significant dense fibrillary component; a frequent, characteristic, often prominent vasocentric pattern of tumor cells attaching to and surrounding blood

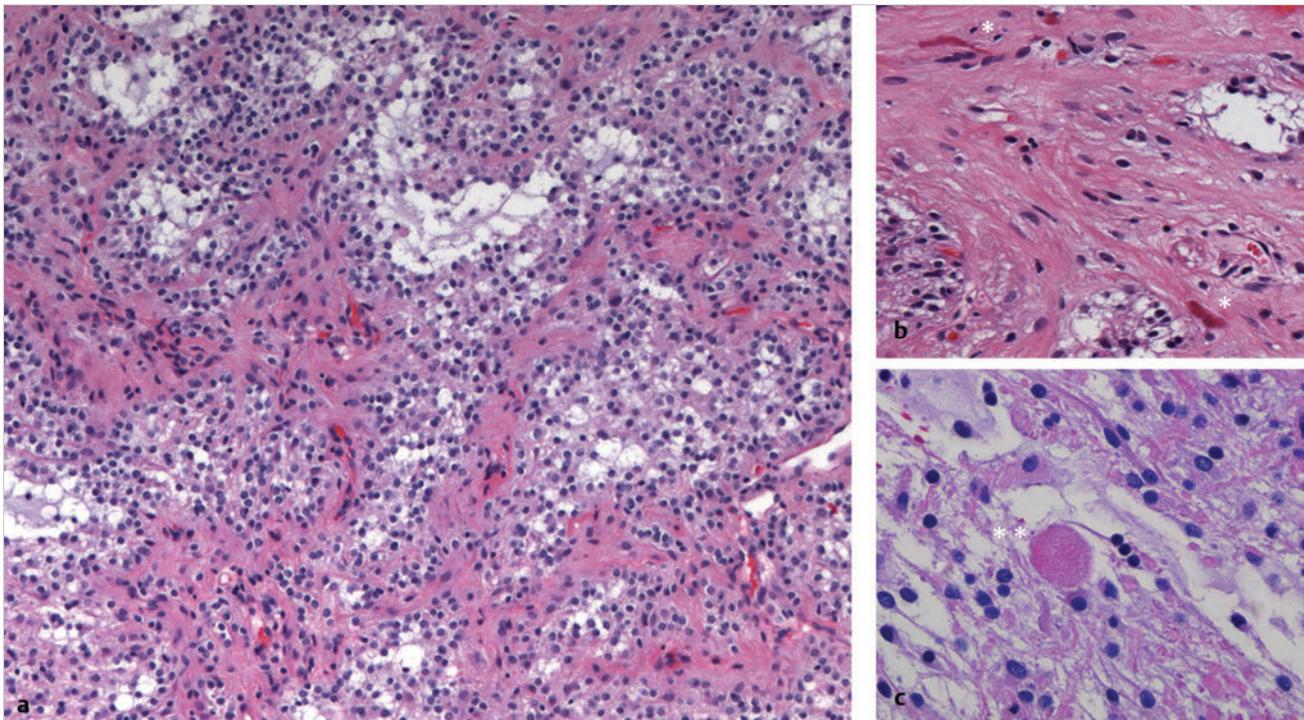

Fig. 43.1 Histologic appearance of pilocytic astrocytoma. (a) Low-power microscopic field after hematoxylin and eosin staining shows the classic biphasic pattern of dense eosinophilic fibrillary areas (pink–red) intermixed with loose mucinous microcystic regions (pale gray–white). (b) At higher magnification, Rosenthal fibers (single asterisks) appear as thick, dense, glassy, and eosinophilic corkscrew-like structures, found mainly in the dense fibrillary areas, whereas (c) eosinophilic granular bodies (double asterisks) appear as round pink granular structures, mainly localized to microcystic areas.

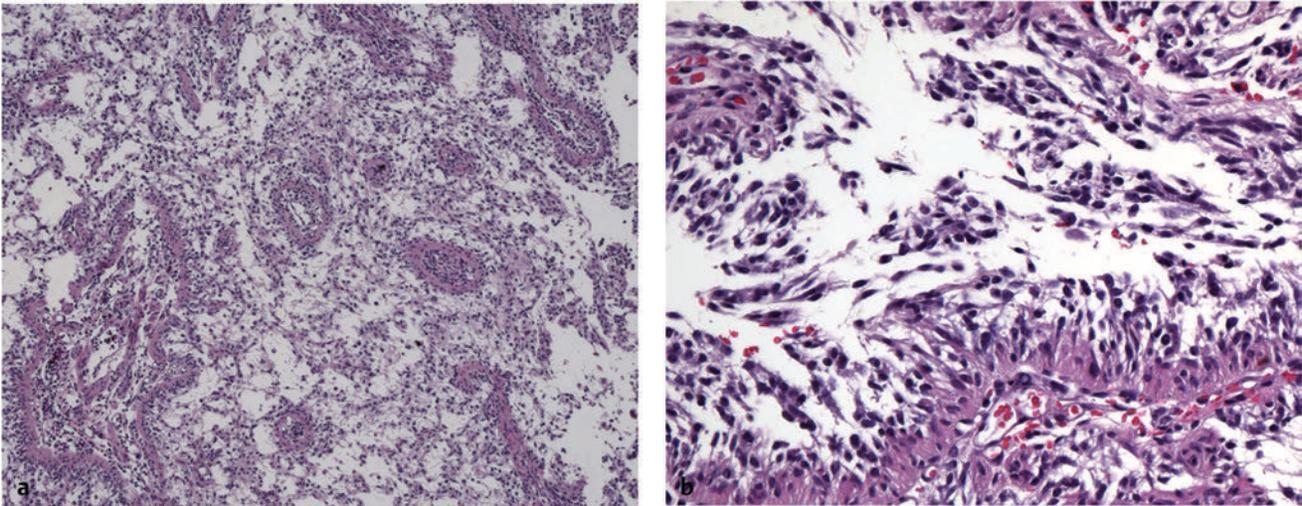

Fig. 43.2 Histologic appearance of pilomyxoid astrocytoma. (a) On low-power microscopy, the tumor is composed of scattered blood vessels within a purely microcystic background, lacking the characteristic biphasic appearance of pilocytic astrocytoma. (b) Characteristic of this tumor is a radial orientation of monomorphous tumor cells adhering to the blood vessel walls; this “angiocentricity” is better visualized at higher magnification. No Rosenthal fibers or eosinophilic granular bodies should be seen.

vessel walls; typically uniform, monomorphic (piloid) bipolar spindle tumor cells; and essentially complete absence of Rosenthal fibers, as well as a severe dearth or absence of eosinophilic granular bodies.^{23,25} Tumor cells are characteristically arranged in a perpendicular fashion around blood vessel walls, revealing a so-called vasocentric or perivascular rosette-like configuration.²⁷ These perivascular collars are usually composed of a single layer of elongated tumor cells, which insert relatively stout processes into the vessel walls. Necrosis is not common but occurs somewhat more frequently than in PA. Calcification is relatively rare in PMA and is occasionally seen in PA. The mitotic index in PMA may be slightly higher than that in PA.²⁵ Occasionally, glomeruloid-type microvascular proliferation may be seen in PMA. Some PMAs appear to “mature” (or perhaps “burn out”) into PAs over time,²⁸ but initial sampling error (i.e., secondary to the receipt of only a small biopsy specimen for pathologic evaluation) may also explain this “phenomenon,” in at least some cases. Much less frequently, the reverse appears to occur (i.e., a PA recurs as an apparent PMA). Whether the latter may occur due to overgrowth of the “loose” component (which often contains tumor cells with a higher overall proliferation index) or results from some sort of transformative event or simply represents sampling error in the initial biopsy is unclear at this time.

Diffuse Fibrillary Astrocytomas

DFA (► Fig. 43.3) are WHO grade II tumors. The major (although variable) features that may help differentiate DFA from PA include more nuclear atypia and hyperchromasia, often less cellularity, and a more homogeneous cellular composition of fibrillary astrocytes (often without a clearly loose/microcystic component).²⁹ The neoplastic cells definitely infiltrate brain. Mitoses should be relatively inconspicuous to absent for this to be classified as WHO grade II.³⁰ Vascularity is much less prominent than in PA and PMA. DFA is much less common than

PA and even PMA in the cerebellum. One helpful finding, which may be seen in smear preparations or sections, may be the increased presence of apoptosis or apoptotic bodies in DFA relative to PA (D.R.B., unpublished observation); otherwise, these two entities (PA and DFA) can be somewhat difficult to differentiate by routine histopathology alone, particularly with smaller samples. Another differentiating feature is that the piloid (long, thin, hair-like) processes typical of PA should not be a prominent feature in cytologic preparations of DFA, but this is not always a readily obvious difference. Most important may be the utilization of radiologic correlation to help differentiate these entities. WHO grade II DFA is nonenhancing and solid (not macrocystic), and it has blurry, infiltrative borders, in contrast to the typically enhancing, macrocystic, and discrete WHO grade I PA. Recently described molecular genetic markers may also be of further help in this differential. The “entity” of “diffuse” pilocytic astrocytoma is also described.^{14,31–33} Most practicing neuropathologists still consider this a WHO grade I neoplasm. This is a PA in which at least some significant portion infiltrates the cerebellum, especially if an infiltrative pattern of growth is noted even within the epicenter of the tumor; infiltration may be best demonstrated by the use of immunohistochemistry with antibodies to neurofilament protein (NFP), which demonstrate many NFP-positive cell processes/axons present within, and especially if present throughout, the specimen. In carefully examined gross total (and other large) resection specimens that are completely or nearly completely submitted for microscopic examination, at least a component of focally “diffuse” or infiltrating pattern is seen in many if not most cerebellar PAs. It is possible for such tumors, when suboptimally examined, to be mistakenly designated as “DFA” and thus “overgraded” as WHO grade II. Recent studies suggest that the biological behavior and overall prognosis for PA and for “diffuse” PA are similar, and that “diffuse” PA does not require any special clinical consideration or intervention in comparison with “classic” PA.^{14,32,33}

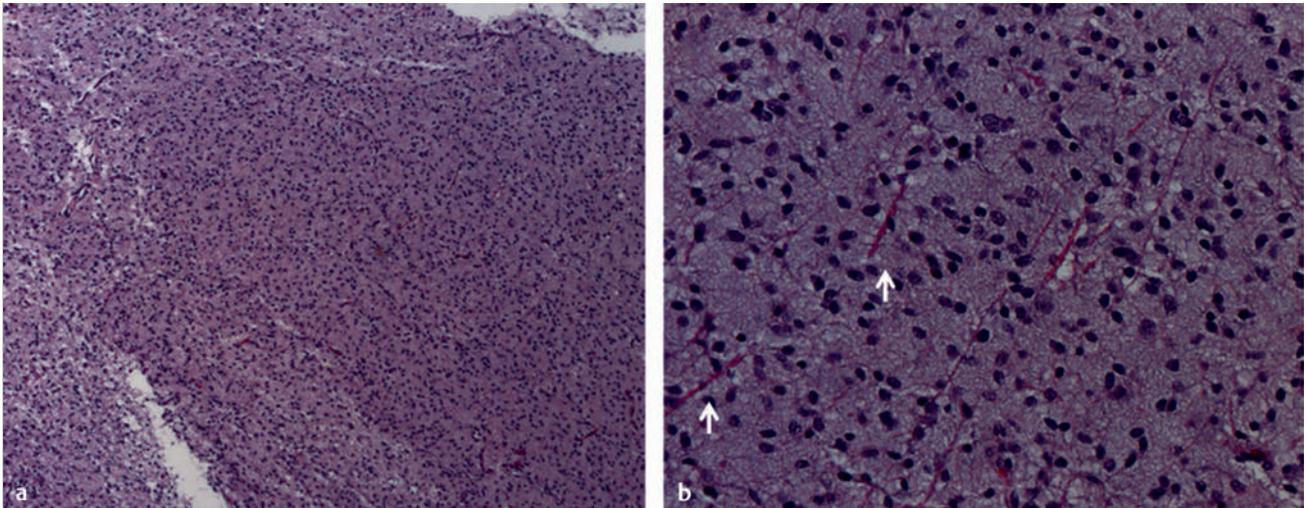

Fig. 43.3 Histologic appearance of diffuse fibrillary astrocytoma (World Health Organization grade II). (a) Low-power microscopy shows a homogeneous cellular pattern, with moderate hypercellularity and minimal pleomorphism and nuclear atypia. At higher magnification (b), it is possible to better observe a background composed of normal (pink) axonal processes (white arrows) demonstrating tumor infiltration into normal tissue. Mitotic activity is not seen.

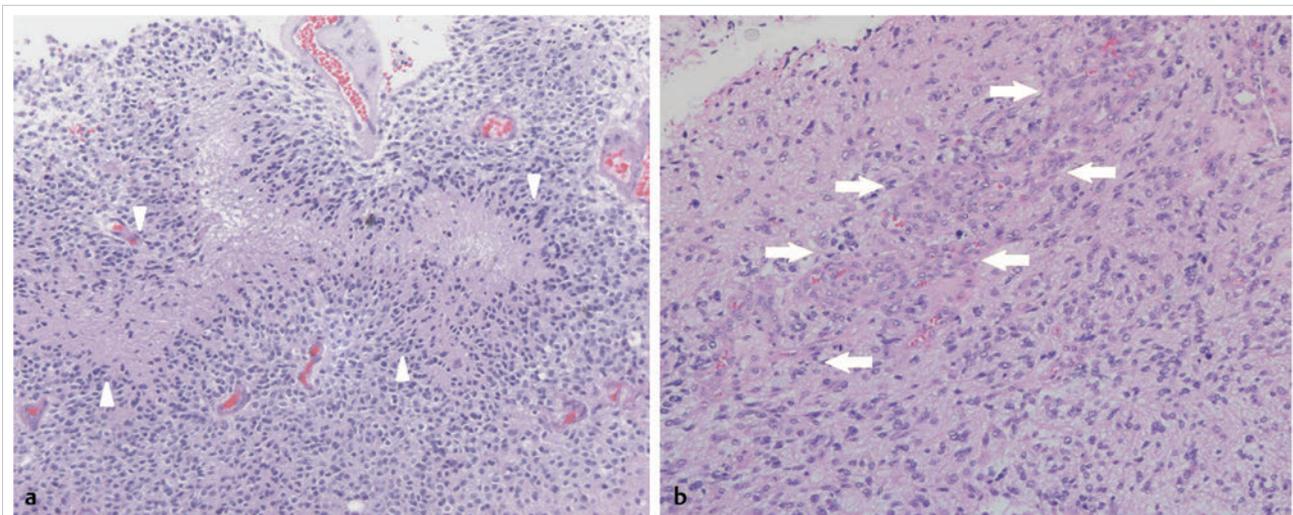

Fig. 43.4 Histologic appearance of glioblastoma multiforme. (a) At low magnification, it is possible to observe the pronounced hypercellularity, nuclear pleomorphism, and characteristic pseudopalisading of viable tumor cells about an area of tumor necrosis (white arrowheads). (b) A focus of vascular endothelial proliferation (white arrows) is causing nearly complete obliteration of blood vessel lumina; this finding (like pseudopalisading necrosis) is pathognomonic for glioblastoma multiforme (differentiating it from anaplastic astrocytoma).

Diffuse Anaplastic Astrocytoma and Glioblastoma Multiforme

These tumors (► Fig. 43.4) are both generally characterized by increased nuclear pleomorphism, hyperchromasia, and increased mitotic activity. Microvascular endothelial proliferation (multilayered “endothelium”) or pseudopalisading necrosis is pathognomonic for GBM.^{13,34} Bona fide “diffuse” (fibrillary, infiltrating) astrocytomas of the cerebellum, although infrequent overall, are more often of a higher grade (WHO grade III or IV rather than WHO grade II).^{14,32}

43.3 Molecular Biology

Because of the frequently benign course of PA after surgical resection, its molecular signatures have not been studied as extensively as those of medulloblastoma, a tumor associated with a much worse prognosis and in need of better alternative therapies. However, the recent notions that not all pediatric cerebellar astrocytomas behave in the same way, that tumor recurrence does happen, and that adjuvant treatments may have to be considered in certain cases have stimulated the need for a deeper understanding of tumor biology.

Pediatric astrocytomas are molecularly different from the other astrocytic tumors that occur in adults. At the cytogenetic level, the karyotype is normal in at least 50 to 70% of cases^{35,36} and in up to 80% when only cerebellar astrocytomas are considered.³⁷ Although adult astrocytomas are often characterized by loss of the short arm of chromosome 17 (17p) and long arm of chromosome 10 (10q), pediatric astrocytomas do not display a consistent karyotypic pattern,³⁸ with the exception of the frequent duplication of chromosome 7q, which has been described in the majority of pilocytic astrocytomas and in 50% of diffuse fibrillary astrocytomas in children. Gain of 7q copy number results in gain of function of the gene *BRAF*.³⁹ Unlike in adult astrocytomas, p53 mutation and loss of *CDKN2A* (p16) are not common findings in pediatric astrocytomas,^{40,41} and *EGFR* amplification is virtually absent.^{38,42}

Among the molecular features that most consistently characterize PAs is the gain of function, by gene duplication, of *BRAF*, a serine/threonine protein kinase that, in turn, activates the MAPK/ERK cascade, leading to cellular proliferation.⁴³ A recent analysis of 49 specimens of PA revealed duplication of the *BRAF* gene in 41 cases (83%), and this was twice as common in cerebellar as supratentorial tumors.⁴⁴ As a proof of the connection to tumor pathogenesis, upregulation of *BRAF* expression in mouse neuroprogenitor cells induced the formation of intracranial PAs in vivo in 91% of cases.⁴⁵ In addition, overexpression of *BRAF* in human neural stem cells induced an initial increase in clonogenic ability and proliferation, which was then followed by progressive cell senescence mediated by activation of p16. This phenomenon, known as oncogene-induced senescence (OIS), is characterized by a paradoxical decrease in cell growth or even total growth arrest initiated by oncogene induction, and it is triggered by the activation of tumor suppressor genes in response to abnormal proliferative stimuli. This observation may explain the often indolent behavior of the majority of PAs and low-grade pediatric astrocytomas, whose cells, although transformed, are still kept under control by the retained expression of major tumor suppressors, including p53 and p16.⁴⁶ This may explain the high percentage of apoptotic cells observed in these tumors,⁴⁷ as the result of the opposed action of proliferative and inhibitory stimuli. Although the association of supratentorial PA with NF-1 has been elucidated, and loss of heterozygosity of *NF1*, the gene encoding the tumor suppressor protein neurofibromin, has been recognized as the hallmark of PAs associated with NF-1, *NF1* mutation has not been observed for sporadic tumors,⁴⁸ suggesting a different molecular origin. A genetic screen comparing NF-1-associated with sporadic PAs revealed 26 genes differentially expressed between the two groups. Of these, *ALDH1L1* expression has been associated with the NF-1-associated histology as well as with the more indolent tumors in general. In particular, *ALDH1L1* downregulation has been found in 89% of PMAs and PAs with atypical features.⁴⁹

With regard to the cell of origin of pediatric astrocytomas, immunostaining for SOX2, a transcription factor associated with “cancer stem cells,” was reported positive in about 10% of cells in 42 of 45 PAs.⁴⁴ This raises the question whether a PA stem cell exists, as demonstrated for medulloblastoma, glioblastoma,⁵⁰ and diffuse pontine glioma.⁵¹ In their seminal work on brain tumor stem cells, Singh et al were able to isolate cells with clonogenic ability from operative explants of PA that were immunoreactive for nestin and CD133, two of

the accepted markers for cellular stemness. However, there has been no validation, to date, that these cells would be able to recapitulate tumor formation in vivo, as has been done for other brain tumors.⁵²

43.4 Clinical Presentation

Posterior fossa tumors in children mainly present with symptoms of increased ICP, regardless of histology. This is due to progressive mass effect leading to obstruction of the fourth ventricle with resulting hydrocephalus, which is present in up to 85% of patients.^{7,10,11,22,25} Headache and vomiting are the two most common symptoms at presentation^{10,22} and are usually more pronounced in the morning because of recumbent position and increased cerebral blood volume secondary to higher PaCO₂.

The presentation also depends on the child's age; in patients younger than 3 years, macrocrania and motor delay are common,¹² whereas in older children, cerebellar signs are prominent and depend on the tumor location. Different from medulloblastoma and ependymoma, which present most commonly with truncal and gait ataxia due to their midline position, astrocytomas frequently present with limb ataxia that is secondary to hemispheric involvement. Papilledema, nystagmus, and diplopia are also frequently observed.^{7,10,11,22}

The time to diagnosis is usually longer than for medulloblastoma because of the slower growth rate of astrocytomas; it ranges from weeks to several months,^{7,10} depending on tumor location. Typically, the symptomatology associated with vermian lesions progresses more quickly than that associated with hemispheric tumors. The sudden onset of symptomatology secondary to intratumoral bleeding has been described.⁵³

43.5 Imaging

Computed tomography (CT) of the head with and without contrast has been historically considered the first diagnostic step for the evaluation of children presenting with symptoms suggestive of posterior fossa pathology (► Fig. 43.5). However, with the exception of the ability to differentiate between astrocytomas and medulloblastomas (decreased X-ray attenuation on unenhanced CT for the former, increased X-ray attenuation for the latter), CT is, in all other regards, inferior to magnetic resonance (MR) imaging of the brain for obtaining an accurate definition of tumor characteristics and anatomy. In our experience, limited MR imaging (axial T2-weighted sequence) serves as a screening examination in symptomatic patients. It can be performed as a safer, fast, and well-tolerated alternative to CT as an initial examination.⁵⁴ If pathology is detected, formal MR imaging of the brain and spine will need to be obtained for surgical planning and prognostication.

Regardless of imaging modality, cerebellar PAs appear as well-demarcated, often sizable lesions occupying the vermis (12.5 to 25%), hemispheres (36 to 40%), or concurrently the vermis and hemispheres (40%).⁵⁵ Radiologically, astrocytomas have been described as presenting with three possible patterns (► Fig. 43.5):

1. Classic cystic astrocytoma presents as a usually large cystic lesion with an enhancing mural nodule but a nonenhancing cyst wall, which is considered nonneoplastic.

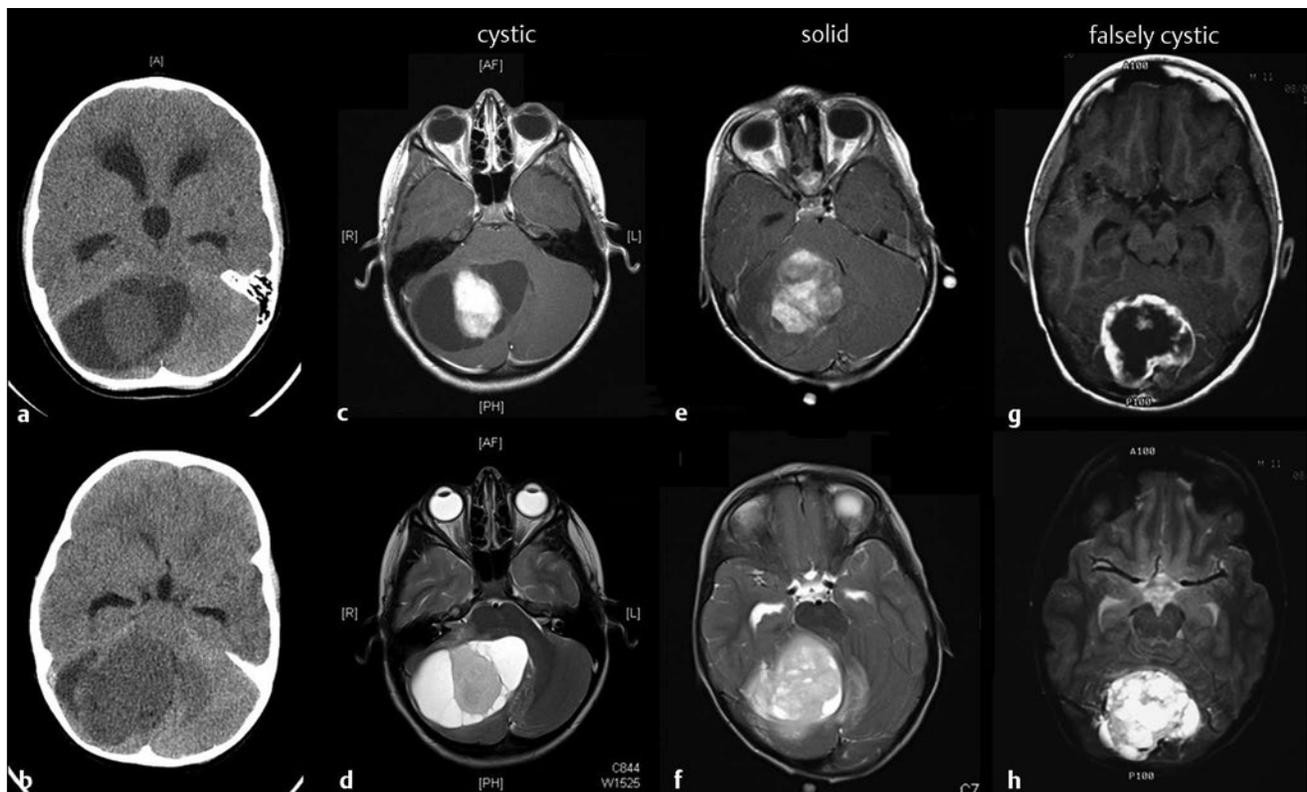

Fig. 43.5 Radiologic appearance of cerebellar pilocytic astrocytoma. Nonenhanced axial computed tomography shows either a hypo- or isodense nodule surrounded by signal, consistent with a fluid-filled cavity (a), or a slightly hypodense and heterogeneous mass in the case of a solid tumor (b). T1-weighted magnetic resonance imaging after the intravenous administration of gadolinium differentiates among “classic” cystic (c), solid (e), and falsely cystic (g) tumors. Neoplastic tissue enhances briskly upon contrast injection. In T2-weighted images, the solid component of the tumor (d,f,h) appears hyperintense to normal brain, a characteristic peculiar to pilocytic astrocytomas.

- False cystic astrocytoma is characterized by the presence of a cystic component within the tumor. The tumor and cyst wall show contrast enhancement. The wall is thicker than 2 to 3 mm and is considered neoplastic.
- Solid astrocytoma is devoid of macroscopic cystic formation and commonly occurs in the vermis.^{7,10,56} Fibrillary astrocytomas usually present as solid masses with less defined borders, suggesting invasion. They most often do not enhance.

Fewer than 10% of PAs invade the brainstem, a behavior more commonly observed with tumors arising in the midline and abutting the fourth ventricle.^{11,57,58} However, the presence and extent of brain stem invasion are usually difficult to predict preoperatively.

On MR imaging, the cystic component of PAs, when present, has a lower T1 signal and a higher T2 signal than that of brain. The mural nodule exhibits increased signal compared with brain on T1 images and enhances brightly and uniformly upon intravenous gadolinium administration. The extent of contrast enhancement of the cyst wall has been considered predictive of its nature; thick enhancement suggests a neoplastic cyst wall, whereas absent or limited enhancement (usually <2 mm in thickness) is more consistent with reactive glial tissue.⁵⁹ However, several authors failed to confirm a strong correlation between radiologic appearance and histology.^{22,60} Solid tumors

usually enhance briskly, but up to 30% of lesions can display areas of decreased or absent enhancement.⁷ Particularly useful for the differentiation between astrocytomas and medulloblastomas are T2 images; the solid component of an astrocytoma consistently exhibits increased signal compared with brain, whereas a medulloblastoma exhibits similar or decreased signal compared with brain.⁶¹ Recently implemented apparent diffusion coefficient (ADC) maps have shown a specificity of 100% in differentiating cerebellar astrocytomas (higher signal intensity) from medulloblastomas (lower signal intensity).⁶² Peritumoral edema is rarely present and does not correlate with prognosis. Intratumoral calcifications are detectable in 25% of cases of PA.⁶³

43.6 Treatment

Cerebellar astrocytoma is a surgical entity, and the primary treatment of cerebellar astrocytomas is surgical resection, with the goal of obtaining total tumor removal. In fact, extent of resection is the main predictor of recurrence and survival.

43.6.1 Preoperative Management

As discussed, children are usually diagnosed when already symptomatic secondary to increased ICP. Because of the potential danger of progressive hydrocephalus, surgical intervention should be planned in an urgent or semiurgent fashion. In those

cases in which obtundation or cardiorespiratory instability is present, immediate intervention with placement of an external ventricular drain is mandatory. In these cases, maximum care needs to be paid to avoid excessive drainage, which can result in upward herniation. The preoperative placement of an external ventricular drain in nonemergent cases is matter of surgeon preference, but in our practice we prefer to avoid it and to start dexamethasone (0.25 to 0.5 mg/kg per day), which usually relieves symptoms in 6 to 12 hours.

43.6.2 Surgical Approach

Positioning is dictated by tumor location and the patient's age. Usually, children younger than 2 years are placed prone with their head resting in a padded pediatric head holder. For older patients, rigid pin fixation is preferred, to increase stability and provide support for retracting devices.

For midline lesions, a vertical skin incision is performed from 1 cm above the external occipital protuberance to the upper cervical spine. An electric knife is then used to separate the posterior muscles of the neck. At this stage, to limit blood loss, care should be taken to cut through the ligamentous midline. Usually, the posterior arch of C1 is exposed but not removed. A suboccipital craniotomy is then performed, just below the transverse sinus and including the opening of the posterior rim of the foramen magnum. The dura is then opened in a Y pattern. It is important, at this stage, to be aware that, particularly in young children, the dura covering the posterior fossa is highly vascularized, so meticulous hemostasis is imperative. Depending on the size of the tumor, the mass effect exerted on the surrounding cerebellum may be substantial. In such cases, opening the cisterna magna is a useful strategy to drain some CSF and decrease ICP. Alternatively, for cystic tumors, a brain needle can be inserted through the dura into the cyst with subsequent aspiration of cyst fluid to achieve decompression.

For vermian lesions, the hemispheres are gently retracted bilaterally until the vermis is exposed and the tumor is visualized. Intraoperative ultrasound can aid in locating smaller tumors. A plane between PAs and surrounding cerebellum is usually well delineated. In order to delineate the anterior margin of the tumor, the fourth ventricle needs to be entered through the foramen of Magendie, so that, by insertion of a cottonoid, the floor of the fourth ventricle is protected during resection. The tumor is then resected piecemeal by aspiration and cautious coagulation. For large, solid lesions, an ultrasonic aspirator (e.g., Cavitron Ultrasonic Aspirator) can be employed. At the final stage, it is important to decide whether the cyst wall is neoplastic or reactive. To this end, when in doubt, multiple biopsies of the wall for frozen histology are recommended. It is preferable to leave the cyst wall in situ when it is not neoplastic.

For lesions located predominantly in the hemispheric region, a retrosigmoid approach may be considered. This has the advantage of sparing the midline structures of the cerebellum, thus preventing possible surgical complications, including cerebellar mutism.

For DFAs, the approach is the same, although the interface between normal tissue and tumor is less well defined. Surgical adjuvants, such as intraoperative frameless stereotaxy and intraoperative MR imaging, may provide useful guidance toward achieving the aim of a gross total resection (GTR).

In closure, the dura should be approximated in a watertight fashion, with the help, if needed, of an appropriate dural substitute. Dural closure is not essential but is advised to decrease the risks for chemical meningitis. Similarly, replacing the occipital bone is advised to decrease the risk for pseudomeningocele formation and to facilitate reoperation in case of tumor recurrence. Finally, it is imperative to meticulously approximate the muscle, fascia, and superficial layers to prevent CSF leakage and pseudomeningocele formation.

43.6.3 Surgical Complications

Postoperative mortality after posterior fossa tumor resection has been reported in the 1.5 to 5% range and is substantially decreased since the advent of modern microsurgical techniques.^{9, 11, 22} Common causes of mortality are surgical site hemorrhage, brain edema, and respiratory compromise secondary to brainstem violation.⁹ Common complications include CSF leakage, pseudomeningocele, meningitis (either infectious or aseptic), cranial nerve palsy, and ataxia.^{6, 10, 22} Cerebellar mutism is a unique consequence of posterior fossa surgery in children. Observed in 11 to 29% of patients, it is more commonly seen after the resection of vermian lesions, which explains why it is almost exclusively observed after medulloblastoma resection.⁶⁴ Brainstem involvement by the tumor may also be a significant risk factor for this complication.⁶⁵ Characteristically, it presents 1 to 6 days after an otherwise uneventful surgery with marked speech delay that is usually of limited duration (1 day to 4 months; average, 6 to 7 weeks). It can also be associated with ataxia, cranial nerve palsy, and emotional lability (the so-called posterior fossa syndrome). Recovery is spontaneous but frequently incomplete, as up to 68% of patients will have persistently impaired speech fluency and dysarthria 1 year after the resolution of mutism. Preoperative evidence of speech abnormalities has been found to be a positive predictor of postoperative mutism.⁶⁶ The pathophysiology of cerebellar mutism is unknown, but most authors agree that it derives from bilateral perturbation of the dentate–thalamocortical pathways with resulting interruption of excitatory stimuli from the cerebellum to supratentorial speech centers. The delayed onset has been explained as resulting from postsurgical hypoperfusion,⁶⁷ edema,⁶⁸ transient deregulation of neurotransmitter release,⁶⁹ or axonal injury caused by sudden release of the tumor mass effect.⁷⁰

43.6.4 Postoperative Management

Intraoperative MR imaging at the end of tumor resection may be used to verify the extent of resection. Otherwise, MR imaging of the brain with and without intravenous gadolinium injection should be obtained within 48 hours of surgery to assess the extent of resection. In this time window, the presence of enhancement is strongly suggestive of residual disease. Depending on the MR imaging findings, the decisional algorithm is as follows: If a GTR has been obtained, no other treatment is indicated, and only follow-up imaging is recommended. There is no consensus, however, on how long the follow-up should be; because recurrence in the setting of GTR is a rare event, some authors have recommended a short follow-up schedule, suggesting only a single imaging session 6 months postoperatively.⁷¹ Contrarily, because of the indolent nature of these tumors, 8 to

10 years has been considered a reasonable period of follow-up by neuroimaging,⁷² although most commonly recurrence or progression happens within the first 5 years after initial treatment.⁷³ If only subtotal resection has been achieved, early reoperation should be considered in cases in which it is deemed safe and feasible because of the survival advantage associated with GTR.⁷⁴

If nonresectable, residual low-grade tumor is present, expectant management with frequent imaging is currently employed at most centers. This is justified by the unpredictable behavior of residual tumors, which not infrequently have been shown to remain stable or even regress at long-term follow-up. In a series of 168 benign cerebellar astrocytomas, Pencolet et al found that 42% of patients who had incomplete resection experienced recurrence, versus 5.6% of patients with initial GTR.²² In another study, of 14 children with residual tumor, 5 had progression, 5 had tumor regression, and the remainder had stable disease at 5 years.⁷³ Gunny et al reported similar results, showing tumor regression in 45% of their patients during a follow-up period of longer than 6 years.⁷⁵

The majority of patients with cerebellar astrocytoma show resolution of the hydrocephalus after tumor resection, although up to 15% will need CSF diversion for progressive hydrocephalus.^{10,76} In comparison, almost half of patients with medulloblastoma require shunt placement.⁷⁶ Other than tumor histology, severe hydrocephalus, the presence of papilledema, and age younger than 2 years have been found to be significant predictors of shunt dependency.⁷⁷ In patients who meet one or more of these criteria, frequent radiologic and clinical assessment is recommended. Indications for CSF shunting include evidence of enlarging ventricles, progressive symptomatology, and persistent CSF leak. Children who receive preoperative ventricular drainage have an increased likelihood to remain shunt-dependent postoperatively.⁷⁸

43.6.5 Adjuvant Therapy

Patients whose tumor is completely resected do not need any further treatment. Chemotherapy and radiotherapy are usually considered in cases in which recurrence ensues or progression of residual disease is observed, if reoperation is not a possibility. Some authors have suggested that repeated resection should be attempted twice before radiotherapy is implemented in these patients.⁴ Others, particularly in light of recent results obtained with focal irradiation, suggest that noninvasive treatment should be favored to decrease surgical risks.

Upfront conventional radiotherapy to incompletely resected grade II gliomas failed to show any survival benefit compared with irradiation at tumor recurrence in a retrospective analysis of 90 patients younger than 20 years.⁷⁹ Also, although usually associated with an excellent tumor response rate, conventional radiation has not been demonstrated to prolong survival.^{73,80,81} For these reasons, the consensus has been to reserve irradiation for relapsing low-grade astrocytomas and for higher-grade astrocytomas and GBM.^{7,13}

More recent series describing results obtained with stereotactic radiosurgery have shown much more encouraging results; 50 patients with a diagnosis of PA who received stereotactic radiosurgery after partial resection or tumor recurrence had a 71% PFS at 5 years and 97.4% survival at 10 years. Small

(<8 cm³) size and solid rather than cystic tumor appeared to be the strongest variables for tumor response.⁸² In another study, 9 of 9 pediatric patients with residual cerebellar PA were progression-free at 5 years after treatment with conformal radiotherapy.⁸³ Finally, in a Phase II trial enrolling patients with low-grade astrocytomas treated with conformal radiotherapy, Merchant et al reported 5- and 10-year PFS rates of 87% and 74%, respectively, with a 10-year survival of 95%. Importantly, in the same series, the authors reported that cognitive impairment occurred only in children younger than 5 years. Other long-term side effects were hearing loss (4.9%), endocrinopathies, and vasculopathies (4.8%).⁸⁴

Chemotherapy remains the front-line adjuvant therapy in infants and young children to defer radiotherapy and its deleterious effect on brain development and cognition. The combination of vincristine and carboplatin demonstrated tumor reduction in 56% of low-grade astrocytomas and a PFS rate at 3 years of 68%.⁸⁵ Similarly, a tumor response in 70% of cases and a 3-year PFS rate of 78% was reported with a combination of cisplatin and etoposide.⁸⁶ For tumors progressing despite prior chemotherapy, temozolomide has been shown to be a promising option, resulting in a 54% response rate and a 49% PFS rate at 2 years.⁸⁷

43.7 Outcome

43.7.1 Prognostic Factors

The only two universally accepted and statistically validated factors associated with survival in patients with cerebellar astrocytomas are (1) low versus high grade and, in the case of low-grade tumors, (2) extent of tumor resection. Gender and age at diagnosis do not correlate with survival.⁷ There is still debate regarding whether low-grade diffuse astrocytomas are associated with worse outcome than PAs; Smoots et al found a statistically significant association of WHO grade II tumors with incidence of residual tumor in the brainstem and, consequently, with poor survival.⁸⁸ This was in agreement with other series, published by Sgouros et al⁸⁹ and Desai et al.¹¹ More recently, results from a series of 200 patients failed to show a significant prognostic value for tumor histology.⁹ Size of the tumor, midline location, and solid appearance have all been associated with worse functional outcome.⁹

43.7.2 Leptomeningeal Dissemination

Fifty-eight cases of disseminated PA have been reported in the literature. The primary tumor was located in the cerebellum in 33% of cases, whereas the majority of cases originated from optic-hypothalamic lesions. PFS rates at 5 years ranged from 50 to 60% with a combination of surgery, radiation therapy, and chemotherapy. Craniospinal irradiation does not seem to be superior to focal radiotherapy and chemotherapy for disease control.¹⁸

43.7.3 High-Grade Gliomas

Malignant cerebellar astrocytomas are rare. When they arise “de novo,” they more frequently affect children younger than

3 years.¹² Alternatively, they may result from malignant transformation of a prior low-grade tumor; malignant transformation of PA has been rarely reported, and in most such cases, it occurred after tumor irradiation.^{90,91} The time window between initial diagnosis and evidence of transformation ranged from 2 to 52 years.⁹⁰ There are 25 cases of primary cerebellar GBM reported in the literature and 8 secondary cases of GBM resulting from malignant transformation of lower-grade tumors,¹³ of which 2 were PAs.⁹⁰ Although symptoms at presentation are similar to those of lower-grade tumors, symptom progression is usually faster, and the diagnosis is made within a few weeks. A tendency for early leptomeningeal spread has also been reported.¹³ Despite aggressive surgical resection and adjuvant therapy, reported mean survival is 10 to 15 months.^{13,92}

43.8 Recurrence/Progression

After GTR, recurrence has been reported in 0 to 6% of patients with low-grade astrocytomas,^{22,71-73,93} with a mean interval of 59 months after surgery.⁷² Following incomplete resection, the rate of tumor progression reaches 50% of cases, and progression usually ensues in the first 3 to 4 years.^{72,73} In the majority of cases, recurrence is diagnosed radiologically rather than clinically, justifying the implementation of long-term radiologic follow-up for patients with incompletely resected tumors.⁹⁴ A recent series reported that 96% of the total recurrences/progressions happened within 8 years from initial surgery, and the authors concluded that radiologic follow-up should thus be extended to that interval.⁷² Although still debated, there does not seem to be a significant difference between recurrence or progression rates for PAs and for diffuse astrocytomas.^{72,94} In case of recurrence, reoperation is strongly recommended because it is associated with an excellent survival if GTR can be achieved^{7,93-95}). When GTR is not a feasible option, subtotal resection followed by adjuvant chemotherapy and/or radiotherapy/radiosurgery is appropriate.

43.9 Survival

Patients in whom complete tumor resection is achieved have an excellent prognosis, with 10-year survival rates ranging from 90 to 100%.^{7,72,89} On the other hand, subtotal resection is associated with a higher likelihood of tumor progression, resulting in 10-year survival rates as low as 50% in some series,^{89,96} although other authors report more favorable outcomes, with up to 85% patients alive at 10-year follow-up.⁷ The mean survival of patients with GBM is 10 to 15 months.¹³

43.10 Functional Outcome

Up to 60% of patients treated for cerebellar PA and followed for a period of 8 years showed permanent neurologic deficits, mainly disequilibrium, strabismus, and ataxia. Furthermore, behavioral disorders, such as irritability and tearfulness, were present in more than 50%.^{97,98} However, in the majority of cases, the deficits did not prevent independent functioning and a high school education.⁹⁷

43.11 Conclusion

Cerebellar astrocytomas are a heterogeneous group of tumors of childhood ranging from completely benign to extremely aggressive lesions. Low-grade tumors (WHO grades I and II) are the most frequent and are generally associated with a very good prognosis. Within this group, there is no agreement on whether PA carries a better prognosis than DFA, but evidence suggests that as long as complete resection is obtained, both have a very benign course, and cure can be very often achieved. The opposite is true for higher-grade tumors. To date, histology and extent of tumor resection are the only two validated predictors of PFS and overall survival; in light of this, the treatment plan for cerebellar tumors should always entail an aggressive approach aimed at complete resection (when this can be achieved with no or minor neurologic sequelae), and then further actions dictated by tumor grading and/or the presence of residual tumor. Patients with completely resected low-grade lesions should be followed by serial imaging. Second surgical resection should be considered for patients with residual tumor or recurrence. If this is not feasible, recent data support a role for stereotactic radiosurgery for local tumor control and extended PFS. Radiation is usually reserved for children older than 5 years of age to limit damage to the growing central nervous system. For younger children, chemotherapy is used. There are no indications to irradiate residual tumor before evidence of regrowth because spontaneous regression has been occasionally described. On the other hand, higher-grade tumors should receive maximum therapy, consisting of chemotherapy and irradiation following surgical resection.

Pearls

- Cerebellar astrocytomas are the second most common posterior fossa tumors in childhood, following only medulloblastomas.
- Histologically, the vast majority are PAs. There is no strong evidence suggesting that low-grade diffuse astrocytoma carries a worse prognosis than PA. High-grade tumors are rare.
- The extent of surgical resection and the histologic grade (low vs. high) are the only validated predictors of PFS and overall survival.
- If GTR is achieved, observation alone is recommended for low-grade tumors.
- If only partial resection of a low-grade tumor is achieved, the remnant should be carefully monitored with frequent neuroimaging.
- Upon recurrence, repeated resection to achieve a GTR is recommended if feasible. Otherwise, radiation therapy should be considered. In younger children, the use of chemotherapy should be implemented to postpone irradiation.

44 Skull Base Tumors

Elizabeth C. Tyler-Kabara, Carl H. Snyderman, and Paul Gardner

Pediatric skull base pathologies and their operative management pose unique challenges for the skull base surgeon. The entities in the differential diagnosis and the ages at presentation are diverse, and the skull base surgeon is faced with a heterogeneous patient population and a dynamic surgical anatomy characteristic of growing patients. Recent advances in imaging and treatments for skull base lesions require careful consideration when applied to the pediatric population. Indications for surgery have expanded to include both benign and malignant disease, and treatments and surgical approaches need to take into account treatment goals, potential long-term side effects of therapy, impact on craniofacial growth, cosmesis, postoperative care, and quality of life.

Pediatric skull base surgery encompasses a wide variety of surgical approaches, both open and endoscopic. There has been a dramatic increase in pediatric endoscopic approaches at our institution, which is a consequence of our experience in the adult population of patients requiring skull base surgery and an increased recognition of the benefits of endonasal surgery for the pediatric population. Decreased morbidity, faster postoperative recovery, and greater patient and family acceptance make endoscopic surgical approaches especially suitable for pediatric patients.

The primary aim of this chapter is to provide an overview of surgical approaches, both open and endoscopic, and their application to common pediatric skull base pathologies. Clinical examples of pathologies affecting different regions of the skull base are discussed, with particular reference to clinical evaluation, the relevant surgical anatomy and approaches, and reconstruction strategies. Specific planning and surgical considerations in the management of pediatric patients with skull base pathologies are highlighted.

44.1 Overview of Skull Base Anatomy

Successful cranial base surgery is based on an in-depth knowledge of the regional and embryologic anatomy of the developing skull base, an understanding of how specific pathologies affect the pediatric skull base, and an appreciation of the limitations and consequences of various surgical techniques in pediatric patients. Extensive training, complemented by dissection work in the laboratory, is crucial to achieve anatomical proficiency, a three-dimensional appreciation of the structural relationships, and a knowledge of anatomical variations. The skull base surgeon must master intracranial, extracranial, and endoscopic surgical anatomy.

The skull base can be considered in three different parts—anterior, middle, and posterior—with closely related intracranial and extracranial anatomical compartments (► Table 44.1). Detailed anatomy is beyond the scope of this chapter. Major considerations include a knowledge of (1) surgical anatomy for optimal access with minimum risk to critical neurovascular structures, (2) developmental anatomy of various growth

stages, (3) embryologic anatomy to understand surgical pathology, (4) vascular anatomy, and (5) reconstructive anatomy.

44.1.1 Anterior Skull Base

This portion of the skull base extends from the internal surface of the frontal bones anteriorly to the sphenoid ridge of the sphenoid bone posteriorly. The latter is joined medially by the chiasmatic groove (► Fig. 44.1). The intracranial surface is formed by the frontal, ethmoid, and sphenoid bones.¹ The frontal bones comprise the major part of the anterior cranial base, contributing to its lateral part. The orbital process of the frontal bone articulates posteriorly with the lesser wing of the sphenoid bone. Those two bones form the orbital roof and the optic canal, which transmit the optic nerve and ophthalmic artery. Posterolaterally, the optic canal is related to the anterior clinoid, and inferomedially to the posterior ethmoid sinus. The frontal sinus lies anteriorly between the external and internal walls (anterior and posterior tables) of the frontal bone.

The anterior cranial base faces the frontal lobes, with the rectus gyrus medially and the orbital gyri laterally. In the midline, the superior sagittal sinus continues to the floor of the anterior cranial base, where it connects with a small emissary vein at the foramen cecum. The fronto-orbital artery, a branch of the anterior cerebral artery, travels along the inferior and medial surface of the frontal lobe and is therefore at risk during anterior cranial base surgeries. The olfactory bulbs lie over the cribriform plates, and the olfactory tracts continue posterolaterally, closely applied to the surface of the brain as they pass over the optic nerves.

The midline of the anterior cranial base is related to the nasal cavity, ethmoid, and sphenoid sinuses. The ethmoid bone constitutes the anterior two-thirds of the midline anterior cranial base. The regions of the ethmoid bone related to the intracranial surface from medial to lateral are the crista galli, cribriform plate, and fovea ethmoidalis. The crista galli separates the anterior half of the cribriform plate in the midline and is attached to the falx cerebri. Anterior to the crista galli, the foramen cecum transmits an emissary vein responsible for the venous drainage from the nasal cavity to the superior sagittal sinus. In addition to the potential risk for the intracranial dissemination of nasal infections, lesions like nasal dermoid, glioma, and meningocele can communicate intracranially via the foramen.^{2,3} The thin lateral lamella of the cribriform plate continues laterally as the fovea ethmoidalis or roof of the ethmoid sinuses. The depth and angulation of the lateral lamella affect the risk for iatrogenic cerebrospinal fluid (CSF) leak during transethmoidal procedures. The olfactory filaments pass through the cribriform plate from the nasal cavity to the intracranial olfactory bulbs and are a route for the intracranial spread of sinonasal malignancy. The posterior third of the midline anterior cranial base is formed by the planum sphenoidale, which corresponds to the roof of the sphenoid sinus.

At the junction of the ethmoid sinus and orbit, the anterior and posterior ethmoidal foramina along the frontoethmoidal suture line transmit the anterior and posterior ethmoidal

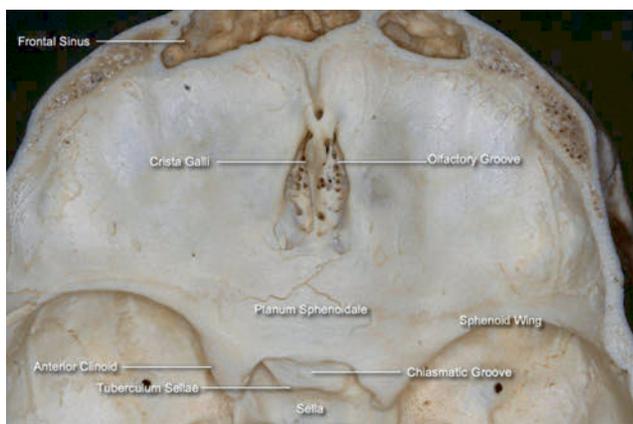

Fig. 44.1 Intracranial view of the anterior cranial base.

arteries, respectively (► Fig. 44.2). These arteries are derived from the ophthalmic artery within the orbit. From the orbit, the ethmoidal arteries enter the ethmoid sinuses via their respective foramina and run in a lateral-to-medial direction in the roof of the ethmoid sinuses. In some cases, they may lie below the ethmoid roof on a bony mesentery or pedicle and are at risk during endoscopic sinus surgery. The anterior ethmoidal artery is located between the second and third ground lamellae in a coronal plane tangential to the posterior surface of the globe. The posterior ethmoidal artery is often found at the junction of the fovea ethmoidalis and planum sphenoidale. These arteries diverge as they cross the roof of the ethmoid and need to be identified and ligated or coagulated during surgical procedures involving the anterior cranial base. Medially, the arteries enter the cranial cavity through the lateral lamella and re-enter the nasal cavity to supply the upper nasal septum.

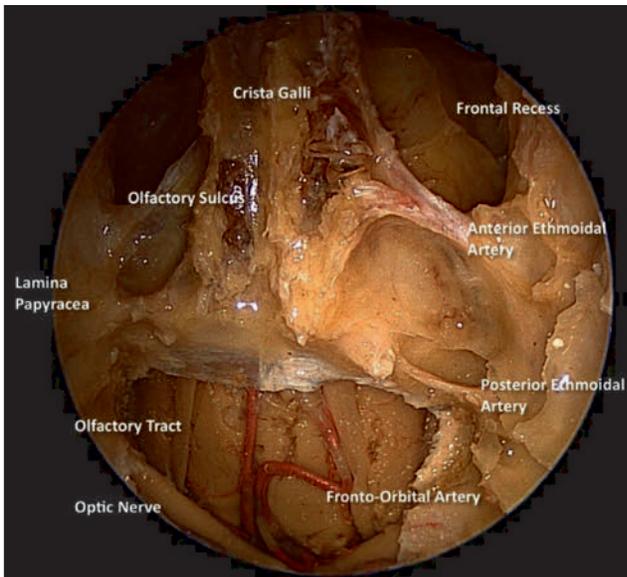

Fig. 44.2 Endonasal endoscopic view of the anterior cranial base demonstrating the relationship of the anterior and posterior ethmoid arteries to the orbit and the skull base.

44.1.2 Middle Cranial Base

The intracranial surface of the middle cranial base is formed by the sphenoid and temporal bones.¹ The limit between the anterior and the middle cranial bases is the sphenoid ridge joined medially by the chiasmatic groove. The transition between the middle and the posterior cranial bases is the petrous ridge joined medially by the dorsum sellae and the posterior clinoid process.¹

The intracranial surface of the middle cranial base can be divided into two regions: medial and lateral. The medial region is composed of the body of the sphenoid bone and is related to the pituitary gland and cavernous sinus, including the tuberculum sellae, pituitary fossa, middle and posterior clinoid processes, carotid sulcus, and dorsum sellae.¹ The greater wing of the sphenoid bone and the temporal bone (squamosal and petrosal segments) form the lateral portion of the middle cranial base, containing the middle cranial fossa. The optic strut runs under the optic nerve and separates it from the internal carotid artery (ICA). Pneumatization of the optic strut forms the lateral opticocarotid recess (OCR), observed endonasally in the sphenoid sinus (► Fig. 44.3).

The temporal bone has a pyramidal shape, the sides of which form the middle fossa floor (superior face), the anterior limit of the posterior fossa (posterior face), the muscle attachments of the neck and infratemporal fossa (anteroinferior face), and the muscular-cutaneous-covered side of the head (lateral), which forms the base of the pyramid. The temporal bone consists of four embryologically distinct components: the squamous, mastoid, petrous, and tympanic parts.

The area below the middle cranial fossa includes the infratemporal fossa, parapharyngeal space, infrapetrous space, and pterygopalatine fossa. The boundaries of the infratemporal fossa are the medial pterygoid muscle and the pterygoid process medially, the mandible laterally, the posterior wall of

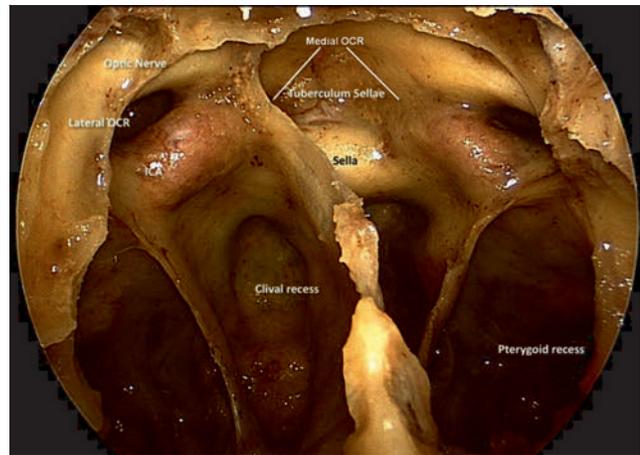

Fig. 44.3 Endoscopic view of the surface anatomy of the sphenoid sinus demonstrating the relationships of the optic canals, internal carotid arteries, and opticocarotid recesses. OCR, opticocarotid recess.

the maxillary sinus anteriorly, the greater wing of the sphenoid superiorly, and the medial pterygoid muscle joining the mandible and the pterygoid fascia posteriorly. The fossa opens into the neck below. The infratemporal fossa contains the branches of mandibular nerve, the maxillary artery, and the pterygoid muscles and venous plexus. The mandibular nerve exits the cranial base through the foramen ovale. The pterygoid venous plexus connects via the middle fossa foramina and inferior orbital fissure with the cavernous sinus and empties into the retromandibular and facial veins.¹ During a lateral infratemporal approach, the following structures form a linear plane superficial to the ICA canal: the lateral pterygoid plate, foramen ovale, foramen spinosum, and spine of the sphenoid. Deep to this linear plane, the eustachian tube overlies the petrous carotid canal.

The pterygopalatine fossa is located between the maxillary sinus anteriorly, the pterygoid process posteriorly, the palatine bone medially, and the body of the sphenoid bone above. The fossa communicates laterally via the pterygomaxillary fissure with the infratemporal fossa and medially through the sphenopalatine foramen with the nasal cavity. Both the foramen rotundum (with the maxillary nerve) and the pterygoid canal (with the vidian nerve) communicate with the pterygopalatine fossa via the posterior wall. The main contents of the fossa include branches of the maxillary nerve and vidian nerve, the pterygopalatine ganglion, and the pterygopalatine segment of the maxillary artery.

The parapharyngeal space is predominantly a fat-filled space but also contains the eustachian tube, pharyngeal branches of the ascending pharyngeal and facial arteries, and branches of the glossopharyngeal nerve. It is divided into two compartments, an anterolateral pre-styloid space and a posteromedial post-styloid space, by fascia from the styloid process to the tensor veli palatini muscle. The pre-styloid space contains the deep lobe of the parotid gland, minor salivary glands, a small branch of the mandibular nerve (cranial nerve V₃) to the tensor veli palatini muscle, the ascending pharyngeal artery, and the pharyngeal venous plexus, embedded in mostly fatty tissue. The post-styloid compartment

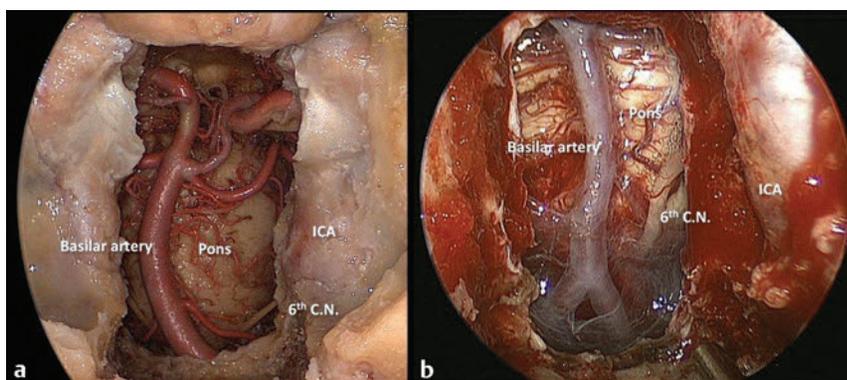

Fig. 44.4 (a) Cadaveric dissection demonstrating the course of cranial nerve VI. The nerve arises from the brainstem at the level of the vertebral-basilar junction. (b) Operative photo demonstrating the course of cranial nerve VI relative to the paraclival carotid artery. The nerve enters the Dorello canal at approximately the midpoint of the paraclival internal carotid artery. ICA, internal carotid artery; 6th C.N., sixth cranial nerve.

contains the ICA, internal jugular vein, cranial nerves IX through XII, the cervical sympathetic chain, lymph nodes, and glomus bodies.

Endonasally, the medial aspect of the middle fossa (Meckel cave) is lateral to the paraclival ICA and superior to the petrous segment of the ICA. The second division of the trigeminal nerve (foramen rotundum) and the vidian nerve (pterygoid canal) are helpful landmarks that define the area of the pterygoid and sphenoid just anterior to this. The Meckel cave is bounded by the lateral cavernous sinus superiorly containing cranial nerves III, IV, V₁, and VI. The foramen ovale is posterior to the lateral pterygoid plate, and the base of the pterygoid requires drilling to gain optimal access to this region.

44.1.3 Sphenoid Sinus

The surface anatomy of the sphenoid sinus is important for endonasal approaches to the pituitary and surrounding areas (► Fig. 44.3). The degree of sphenoid pneumatization and the patterns of septa vary greatly. Lateral septa almost always deviate toward the ICA, and care must be taken when they are removed. The sella is bounded by the clival recess inferiorly, cavernous sinus and ICA laterally, and optic canal superolaterally. The clival recess is bounded by the paraclival ICA and petrous apex laterally. The sixth cranial nerve courses superolaterally in the Dorello canal behind the paraclival ICA and is at risk for injury during drilling posterior to the paraclival ICA just below the level of the sellar floor (► Fig. 44.4).

44.1.4 Posterior Cranial Base and Craniocervical Junction

Surgical access to the posterior cranial fossa may be posterior, inferior, and medial to the temporal bone. The sigmoid sinus defines the posterior margin of the petrous temporal bone. The infrapetrosal space contains the jugular bulb and the lower portion of the inferior petrosal sinus; branches of the ascending pharyngeal artery; the glossopharyngeal, vagus, and accessory nerves; and the opening of the carotid canal through which the ICA enters the cranial base. Endonasally, the clivus lies anterior to the brainstem and can be divided into three segments: superior, middle, and inferior. The superior segment extends from the posterior clinoid to

Table 44.2 Flaps and their blood supply

Flap	Blood supply
Septal flap	Posterior septal artery
Pericranial flap, galeopericranial flap	Supraorbital and supratrochlear arteries
Temporoparietal flap	Superficial temporal artery
Temporalis muscle flap	Deep temporal arteries
Inferior and middle turbinate flaps	Branches of sphenopalatine artery
Palatal flap	Descending palatine artery

the sella floor and intracranially is related to the oculomotor nerve and posterior cerebral and superior cerebellar arteries. The middle segment extends from the sellar floor to the floor of sphenoid sinus and is related to the abducens nerve and the basilar and anterior inferior cerebellar arteries. The inferior segment extends from the floor of the sphenoid sinus to the foramen magnum and is related to the glossopharyngeal, vagus, and hypoglossal nerves and the vertebral-basilar junction. Inferolaterally, the hypoglossal foramen is bounded superiorly by the jugular tubercle and the occipital condyle inferiorly.

44.2 Reconstructive Anatomy: Pedicled Flaps

Major reconstructive options include the nasoseptal and scalp flaps. The latter encompass the pericranial, galeopericranial, temporoparietal, and temporalis muscle flaps. Another flap that may be used is the inferior turbinate flap. The middle turbinate and palatal flaps are generally not a practical option in the pediatric population. A summary of vascularized flaps and their blood supply is provided in ► Table 44.2.

44.2.1 Scalp

Understanding the layers of the scalp makes it possible to preserve function and plan reconstruction with pedicled scalp flaps. The scalp has five layers, designated by the acronym SCALP: skin, subcutaneous tissues, aponeurosis (galea),

loose areolar layer, and periosteum. The pericranial flap comprises the loose areolar layer and periosteum, whereas the galeopericranial flap includes the galeal layer. The pericranial flap is supplied by the supraorbital and supratrochlear vessels, which exit foramina or notches along the superior orbital rim. Laterally, the galea is continuous with the superficial temporal fascia. A temporoparietal flap, derived from this layer, receives its blood supply from the superficial temporal artery. The temporalis muscle, another important reconstructive flap, is covered by the deep temporal fascia. The deep temporal arteries, terminal branches of the internal maxillary artery, supply the muscle on its deep surface.

44.2.2 Nasoseptal Flap

The nasoseptal flap is pedicled on the posterior septal branches of the sphenopalatine artery, which run across the anterior surface of the sphenoid rostrum below the level of the sphenoid ostium and immediately above the choanal margin. The superior incision extends posteriorly from the level of the sphenoid ostium and is carried forward anteriorly along the nasal septum below the skull base. The inferior incision extends from the posterior choanal margin, curving medially along the posterior margin of the vomerine septum to the nasal floor, and is carried anteriorly along the junction of the nasal septum and nasal floor. The superior and inferior septal incisions are then joined with a vertical septal incision at the squamocolumnar junction. This mucoperichondrial, mucoperiosteal nasoseptal flap is then elevated off the cartilaginous and bony nasal septum. Further surgical details of the nasoseptal flap can be found elsewhere.⁴ This flap can be used to reconstruct defects of the anterior (cribriform plate, fovea ethmoidalis, planum), middle (sellar, lateral sphenoid recess), and posterior (clival, craniocervical junction) cranial base.

44.3 Vascular Anatomy

In many respects, the surgical approaches to the skull base and reconstruction with vascularized flaps are determined by the vascular anatomy. Detailed vascular anatomy allows the anticipation and avoidance of injury to critical vessels, including the ICA, basilar artery, circle of Willis, perforators, superior hypophysial, fronto-orbital, and ophthalmic arteries. It also allows the anticipation and ligation of critical vessels required to devascularize the surgical field, including the anterior and posterior ethmoid, sphenopalatine, and internal maxillary arteries.

The course of the ICA has particular relevance during approaches to the middle cranial fossa. The suprapetrous and infrapetrous approaches are defined as above and below the horizontal (petrous) segment of the ICA, respectively. At least five segments of the ICA have been described: parapharyngeal (extracranial), horizontal (petrous), paraclival, cavernous, and supraclinoid.⁵ Surgical landmarks are described in detail elsewhere.⁵ The ophthalmic artery branches off the ICA as it exits the cavernous sinus and runs inferomedial to the optic nerve. The circle of Willis comprises the ICAs, anterior cerebral arteries, anterior communicating artery, posterior cerebral arteries, and posterior communicating artery. A patent circle of

Willis is predictive of collateral cerebral blood flow, and anatomical variations are common.

44.4 Developmental Anatomy

Several important considerations include the development of certain pathologies, potential disruption of craniofacial growth with various surgical approaches (especially open) and anatomical limitations to surgical approaches in the growing pediatric patient. The latter is particularly important when considering transnasal approaches to the skull base, where development of the sinuses and configuration of the piriform aperture can limit access. Importantly, when considering transsphenoidal pituitary surgery, sphenoid sinus pneumatization can affect intercarotid distances and determine the amount of drilling to access the sellar. Furthermore, the development of the nasal septum relative to the cranium can limit the size of nasoseptal flaps for reconstruction.⁶

44.4.1 Skull Base and Facial Skeleton

There are three main components of the human skull: (1) the membranous neurocranium containing the flat bones of the skull, (2) the cartilaginous neurocranium forming the major part of the skull base, and (3) the viscerocranium or facial skeleton.⁷ The precursor of the cranial base is a cartilaginous plate, the chondrocranium, which subsequently undergoes endochondral ossification. The cranial base has two portions with distinct embryologic origins: the anterior part and the posterior part, derived from the neural crest and paraxial mesoderm, respectively. The anterior and posterior parts of the cranial base are separated by the sella turcica.

The anterior cranial base integrates with the mid and upper face to form a coordinated growth complex and serves as a template for facial growth. It carries the mid and upper face forward, inferiorly, and laterally. It grows at a faster rate than the posterior cranial base, and the growth occurs predominantly in the sphenothmoidal synchondrosis and in the cartilage between the ethmoid and frontal bones. From adolescence onward, progressive pneumatization of the frontal and ethmoid bones contributes to the rest of anterior cranial growth. Thus, anomalies of anterior cranial growth (including cretinism, Turner syndrome, and Down syndrome) and surgery of the anterior cranial base that disrupts critical growth centers affect both cranial and facial growth. In such cases, the craniofacial structure is characterized by a short, retrognathic face due to reduced length of the cranial base and increased angulation between the anterior and posterior cranial base.

In contrast, the mandible articulates with the posterior cranial base, and variation of the growth and orientation of the cranial base can affect jaw position and occlusion. Mandibular prognathism has been attributed to abnormalities of posterior cranial base growth.

Skeletal maturation of the skull shape begins with the midline cranial base (7.7 years), followed by the lateral skull base (11.7 years), and finally the face (15.7 years).⁸ Hence, a definitive adult shape of the basicranium is obtained at approximately 12 years. The maturation of craniofacial size follows a superior–inferior gradient, beginning at the neurocranial outline in the midline (11.4 years), followed by the midline cranial base (13.6 years) and the lateral cranial floor and face (15.7 years).

During development of the primitive frontal nasofrontal process (the anterior neuropore), two openings become apparent. The fonticulus frontalis appears between the frontal and nasal bones, while the foramen cecum appears as a midline opening anterior to the crista galli. A diverticulum of dura projects through the fonticulus frontalis or through foramen cecum into the prenasal space, which is found inferior and posterior to the frontal and nasal bones but superior and anterior to the septal cartilage. The dura temporarily approximates the skin and subcutaneous tissues of the midnasal bridge at the osseous cartilaginous junction. Failure of the involution of this diverticulum can lead to the development of nasal dermoid sinus cysts, nasal gliomas, and meningoencephaloceles. All of these lesions have in common certain elements of disjunction or failed primary neurulation of the anterior neuropore. Craniofacial malformations have been reported to varying degrees in all three conditions, and magnetic resonance (MR) imaging is the imaging modality of choice for all these lesions.

44.4.2 Sella and Pituitary Gland

The pituitary gland is ectodermal in origin and has dual embryologic development. The anterior and intermediate lobes develop from oral ectodermal elements derived from the Rathke pouch, and the posterior lobe develops from neural ectoderm. An invagination (Rathke pouch) forms from the primitive stomodeum, cranial to the buccopharyngeal membrane, and extends toward the invagination derived from the neuroectoderm (infundibulum). The anterior portion of the Rathke pouch epithelium proliferates to form cells of the adenohypophysis, while the posterior portion remains largely as a cleft (intermediate lobe) between the anterior and posterior (neurohypophysis) lobes.

Neoplasms arising from the anterior lobe are classic pituitary adenomas, and their phenotype depends on the proliferating cell type. An accumulation of epithelial secretions from the intermediate lobe is thought to underlie the pathophysiology of Rathke cleft cysts. Although still debatable, the general consensus is that craniopharyngioma arises from the neoplastic transformation of cells in the Rathke cleft. Given the close relationship between the cells of origin of these pathologies, adenomas may occur simultaneously with Rathke cleft cyst.⁹

44.4.3 Frontal, Ethmoid, and Maxillary Sinuses

The paranasal sinuses develop at different stages, which is important to keep in mind, especially when endonasal (transnasal, transsinus) approaches to the skull base are being considered. The ethmoid and maxillary sinuses are present at birth and are well developed by 3 years of age. The frontal sinus develops at approximately 7 years of age and becomes fully pneumatized by 12 years.

44.4.4 Sphenoid Sinus

Sphenoid sinus pneumatization begins after age 2 at the anteroinferior wall of the sphenoid bone. A recent study showed that by 6 to 7 years of age, the sphenoid anterior wall is fully pneumatized in all patients, and 88% of the planum is pneumatized.^{10,11} The sella turcica and middle cranial fossa portion of the sphenoid bone in 6- to 7-year-old patients on average had 77% of the anterior sellar wall and 32% of the sellar floor pneumatized. There was no dorsum pneumatization in 84% of patients younger than 16 years, and the sellar floor length in patients younger than 2 years was 66% of that in adults. Pneumatization in the superior clivus and posterior cranial fossa aspect begins after the age of 10 years.

The intercarotid distance at the level of the cavernous sinus is significantly narrower in patients up to 6 to 7 years old than it is in adults, whereas there is no significant difference in patients 9 to 10 years and older.^{10,11} At the level of the superior clivus, the distances are similar in pediatric and adult patients.

Although incomplete sphenoid sinus pneumatization necessitates more drilling, the early maturation of the intercarotid distances and the use of intraoperative imaging are not a contraindication to endonasal approaches to the sella in pediatric patients. It is also important to consider the age-specific length of the pituitary fossa, which increases by more than 50% from age 2 to adulthood.

44.5 Pediatric Skull Base Tumors

A wide variety of skull base pathologies can affect pediatric patients (► Table 44.3). Tumors and other lesions may arise within the skull base, traverse the cranial base with either intracranial or extracranial origins, or present in single or multiple sites.

Table 44.3 Skull base pathology

Anterior cranial base, nasal cavity, maxillary sinus, orbit	Middle cranial base, sphenoid, sella, infratemporal fossa	Posterior cranial base
Meningoencephalocele	Meningoencephalocele	Chordoma
Nasal dermoid	Pituitary adenoma	Vestibular schwannoma
Glioma	Craniopharyngioma	Epidermoid cyst
Mucocele	Cholesterol granuloma	Glomus jugulare
Juvenile angiofibroma	Trigeminal schwannoma	Osteomyelitis
Fibrous dysplasia	Angiofibroma	
Fibro-osseous tumors	Sarcomas	
Esthesioneuroblastoma		

The latter is characteristic of hereditary tumors, metastatic deposits, and developmental anomalies. These pathologies can involve the anterior, middle, and posterior skull base and the corresponding intracranial fossae and extracranial regions, which include the nasal cavity, paranasal sinuses, orbits, pterygopalatine and infratemporal fossae, pharynx, and parapharyngeal and craniocervical regions. The differential diagnosis depends on age, sex, associated developmental anomalies, location, and clinical and imaging characteristics.

44.5.1 Clinical Presentation and Differential Diagnosis

The clinical presentation is influenced by the age at presentation and by the nature and site of the lesion. The term *congenital* refers to a presentation at or within 1 month of birth and does not indicate the pathophysiology. Often, congenital lesions consist of developmental anomalies; however, hamartomas, choristomas, and teratomas may also present congenitally. The symptomatology is diverse, and in-depth knowledge of the anatomy and cranial nerve physiology is imperative for a correct clinical topographic diagnosis. An adequate clinical examination can indicate the location and estimate tumor extent. However, this may not always be possible in the very young. Endocrine symptoms such as failure to thrive, short stature, and lack of sexual development often predominate in children with pituitary pathologies. Furthermore, nonspecific symptoms, including headache, weight loss, vomiting, weakness, and loss of appetite, may also occur. Symptoms characteristic of lesions involving the anterior, middle, and posterior skull base are summarized in ► Table 44.4.

The physical examination should include a complete assessment of cranial nerve function. In patients with nasal congestion, rhinorrhea, or airway obstruction, an evaluation by otolaryngology should be performed and should include nasal endoscopy. In patients with olfactory dysfunction, objective documentation can be performed. Visual symptoms should be evaluated further by an ophthalmologist and may include visual field testing in addition to a routine examination. Symptoms of hearing loss or vestibular dysfunction can be evaluated further with audiometric testing and vestibular tests if necessary. Lower cranial nerve dysfunction may require an evaluation of swallowing function and aspiration

risk with a functional endoscopic examination of swallowing (FEES) examination or radiography (barium esophagogram). If CSF rhinorrhea is suspected, provocative tests including a Valsalva maneuver can be performed. Testing of collected fluid for β_2 -transferrin or beta trace protein will confirm the presence of CSF.

44.5.2 Imaging in Skull Base Surgery

Computed tomography (CT) and MR imaging provide complementary information regarding the bone and soft-tissue anatomy, respectively, for diagnosis, preoperative planning, the intraoperative period, and postoperative surveillance. Bone erosion, defects, remodeling, hyperostosis, and calcification are well recognized on CT scans. CT angiography is especially helpful to evaluate the vasculature within and surrounding a tumor and is preferred for intraoperative navigation. MR imaging is superior for delineating intracranial or intraorbital invasion and determining the nature of the lesion. Fluid collections (meningocele, obstructed sinus) appear bright on T2-weighted sequences, although chronic sinus obstruction with a high protein content may appear dark on both T1 and T2 sequences. Fat appears bright on T1 and dark on T2 images, which explains the MR imaging appearance of lesions with a high lipid content, such as cholesterol granulomas. Chondromatous neoplasms (clival chordomas, chondrosarcomas) characteristically enhance on T1-weighted MR images with contrast and exhibit a high signal on T2-weighted sequences. Special sequences, such as diffusion-weighted imaging (DWI), are helpful in confirming an epidermoid tumor.

The vascularity of tumors is demonstrated by tumor enhancement on CT with contrast and flow voids on MR imaging. Nasopharyngeal angiofibromas classically enlarge the pterygopalatine fossa and appear as an enhancing lesion with contrast on both MR imaging and CT. Angiography is used to confirm the diagnosis of highly vascular tumors (angiofibroma, paraganglioma) and for the preoperative embolization of feeding vessels.

Preoperative imaging (CT angiography and MR imaging) also provides information regarding the intracranial circulation and collateral cerebral blood flow (patency of the circle of Willis). If sacrifice of the ICA or another major vessel is anticipated or planned, a preoperative balloon test occlusion with neuromonitoring is performed. Additional measures of cerebral blood flow,

Table 44.4 Signs and symptoms

Anterior skull base	Middle skull base	Posterior skull base
Olfactory dysfunction <ul style="list-style-type: none"> • Quantitative (hyposmia, anosmia, hyperosmia) • Qualitative (dysosmia) Proptosis Epiphora Nasal obstruction Epistaxis Facial deformity Diplopia Blurred vision Facial numbness Sinusitis Personality changes	Pituitary dysfunction Visual field loss Trigeminal neuralgia or numbness Facial palsy Ptosis Diplopia Trismus Eustachian tube dysfunction Temporal bone involvement (hearing loss, tinnitus, vertigo)	Tinnitus Hearing loss Balance problems Swallowing difficulties Hoarseness Speech problems Dysarthria Shoulder weakness Various syndromes

including perfusion CT and perfusion MR imaging, provide further objective assessment.

Positron emission tomography (PET) shows cellular activity in the body, primarily through the detection of labeled glucose taken up by the tissues under examination. This may be combined with CT (PET-CT) to give a better anatomical definition. Although this technique eventually may be useful for the identification of primary tumors, it is most appropriate for the detection of metastasis and local recurrence of high-grade malignancies.

44.5.3 Operative Management

The choice of a surgical approach depends on the diagnosis, surgical goals, surgical access, reconstructive options, patient comorbidities, experience of the surgical team, potential complications, and available resources. Goals for surgery are outlined in the box “Surgical Goals in the Pediatric Patient (p.294).” The optimal approach is one that provides adequate access and superior visualization and minimizes potential morbidity, especially that associated with manipulation of the neural and vascular structures, including retraction of the brain.

Surgical Goals in the Pediatric Patient

- Diagnostic biopsy
- Curative surgery
- Palliation, including pain management
- Salvage surgery, including after radiotherapy, chemotherapy, and chemoradiotherapy
- Tumor debulking, for decompression before chemoradiotherapy

Skull base surgery is team surgery and requires the close coordination of team members. Both CT and MR imaging are used for intraoperative navigation, which aids anatomical localization during the surgery, including identification of important neural and vascular structures, determination of tumor margins, and assessment of the extent of resection. Intraoperative imaging (intraoperative CT or MR imaging) is sometimes performed to assess the extent of tumor resection, detect complications (including hemorrhage), or visualize residual tumor by updating the navigation scan following the shift associated with tumor resection.

Neurophysiologic monitoring of cortical function with somatosensory evoked potentials (SSEPs) provides an overall assessment of cerebral perfusion, which can be adversely affected by hypotension or subdural collections (air or fluid).¹² Brainstem evoked response is used to monitor brainstem function during surgeries of the posterior fossa and electromyography to monitor the motor function of cranial nerves.

44.5.4 Surgical Approaches

Approaches to the Anterior Cranial Base

Surgical approaches to the cranial base can be classified based on the anatomical region (► Table 44.5). External approaches are classified by cranial fossa, whereas endonasal approaches are classified as surgical modules in the sagittal and coronal planes. In open approaches, craniofacial osteotomies provide access to the cranial base and help minimize brain retraction.

Anterior Cranial Base: Craniofacial Resection

Historically, the craniofacial approach pioneered by Ketcham and others has been the standard surgical option for the treatment of anterior cranial base pathology. This consists of a transcranial approach combined with a transfacial approach. A bicoronal incision is made over the vertex of the scalp from ear to ear. Laterally, the incision may be extended inferiorly in the preauricular skin crease to increase exposure. The posterior scalp flap can be elevated in a subgaleal plane to expose extra pericranium if needed for reconstruction. The anterior scalp is elevated from the underlying cranium with separation of the periosteum from the deep temporal fascia of the temporalis muscle at its margin. Laterally, the superficial layer of the deep temporal fascia is incised several centimeters above the zygomatic arch, and the interfascial fat pad is elevated with the scalp to avoid injury to the temporal branches of the facial nerve.

At the level of the superior orbital rims, the supratrochlear and supraorbital neurovascular bundles are carefully dissected free from their respective foramina to preserve the blood supply of a pericranial flap; small osteotomies may be necessary if the foramina are complete. Periosteum is elevated from the orbital roofs, glabella, and nasal bones, and the scalp is retracted inferiorly.

A bifrontal craniotomy is performed that encompasses the anterior and posterior tables of the frontal sinus. In the traditional anterior craniofacial resection craniotomy, the inferior osteotomy is placed just above the prominence of the brow. To minimize brain retraction, the supraorbital bar, including the superior orbital rims and glabella, can be removed in a single unit (subfrontal approach). Removal of the supraorbital bar requires elevation of the frontal dura from the orbital roofs. A reciprocating saw is used to transect the orbital rims at the lateral margin of the craniotomy. The orbital contents are protected while the orbital roof is transected with a drill and the bone is drilled anterior to the crista galli. For the subfrontal approach, a final transverse bone cut at the nasion transects the frontal recess and frees the bone segment.

The dura is separated from the crista galli and incised anteriorly to the cribriform plate and laterally along the medial margin

Table 44.5 Summary of surgical approaches to the cranial base

Approach type	Anterior cranial base	Middle cranial base	Posterior cranial base
Open	Craniofacial resection Subfrontal or subcranial craniotomy	Lateral infratemporal skull base approach	Retrosigmoid craniotomy Far lateral cervical approach
Endoscopic	Endonasal resection of anterior cranial base Endonasal transplanum, transcribriform approach	Endonasal suprapetrous approach	Endonasal transclival and transodontoid approach Endonasal infrapetrous approach

of the orbit. The olfactory bulbs and tracts are dissected free from the frontal lobes, and the olfactory tracts and dura are incised posteriorly over the planum. The bone margins are then drilled to communicate with the sinuses, staying anterior to the optic canals.

Frequently, the craniofacial resection combines transfacial approaches with the bifrontal craniotomy. The aim of the transfacial approaches is to provide an adequate field for the dissection and resection of the lesion from the nasal cavity, paranasal sinuses, and orbit. Options include a lateral rhinotomy, midfacial degloving, and an endoscopic endonasal approach. In a lateral rhinotomy, a skin incision is started at the midpoint between the nasal dorsum and the medial canthus. The incision respects facial subunits and extends along the lateral surface of the nose to the nasal alar, then curves around the nostril to the nasal sill.^{13,14} The incision communicates with the nasal cavity along the piriform aperture. Additional exposure can be obtained by extending the incision with a subciliary or transconjunctival incision superiorly (Weber-Ferguson incision), or by incising the upper lip along the lateral philtrum. After exposure of the facial skeleton through these incisions, osteotomies are performed according to the location and size of the tumor. In most situations, except when subcutaneous tissue and skin are involved, in which case skin incision is required, the exposure afforded by these transfacial incisions can be easily obtained by other means (midfacial degloving or endoscopic endonasal approaches). Thus, lateral rhinotomy is rarely used.

The midfacial degloving approach avoids a facial incision and provides better bilateral exposure. A mucosal incision is made in the gingivolabial sulcus, and periosteum is elevated from the anterior maxilla. The incision communicates with the nasal cavity along the piriform aperture, and the nasal soft tissues are elevated from the anterior edge of the nasal septum following a full transfixion incision. Bilateral transmaxillary antrostomies and medial maxillectomies provide additional exposure. The midfacial degloving approach may be supplemented with endoscopy to provide better visualization.

After the appropriate transfacial or endoscopic approach, the tumor is removed en bloc, if possible, by dissecting around the periphery of the neoplasm with opening of the sinuses and transection of the nasal septum. The cranial base specimen is then mobilized through the bone cuts in the cranial base and delivered transcranially.

Reconstruction of the resultant defect is necessary to provide separation of the cranial and nasal cavities and prevent CSF leak, meningitis, and pneumocephalus. The dural defect is repaired primarily. Suitable materials include synthetic dural substitutes, fascia lata, temporalis fascia, pericranial graft, and cadaveric pericardium. An inferiorly based pericranial flap is then reflected posteriorly to cover the entire defect in the anterior cranial base. Rigid reconstruction with a bone graft or alloplastic material is not necessary. It is important to place the flap inferior to the replaced supraorbital bar, with a small gap left to prevent compression of the vascular pedicle.

Anterior Cranial Base: Endoscopic Endonasal Resection

Endoscopic endonasal techniques can be used for the resection of sinonasal malignancies. The intranasal portion of the tumor

is first debulked to provide visualization of the margins and assess the extent of the tumor. Uninvolved sinuses are opened to allow visualization of the medial orbits, nasofrontal recesses, and sphenoid sinus. Bony landmarks (optic canals, carotid canals) are identified and the margins of resection are defined. In most cases, this includes the posterior wall of the frontal sinus, the medial walls of the orbit, the roof of the sphenoid sinus, and the nasal septum. The nasal septum is transected inferior to the area of tumor involvement from the frontal sinus to the rostrum of the sphenoid bone. Margins from the nasal septum mucosa are sent for frozen section analysis. If the septal mucosa is not involved by the tumor, a septal flap can be harvested for later reconstruction.

After harvesting of the septal flap, bilateral frontal sinusotomies are performed with removal of the floor bilaterally (Draf III procedure). The bone of the medial orbit is removed on the side of greatest tumor involvement. The tumor is devascularized by sacrifice of the anterior and posterior ethmoid arteries bilaterally. The arteries are identified at the junction of the orbit and skull base and are cauterized with bipolar electrocautery or ligated with hemoclips.

The bone of the anterior cranial base is thinned with a drill to facilitate the elevation and removal of bone, allowing full exposure of the dura and the area of dural invasion. Bone removal extends from the crista galli to the planum sphenoidale and to the medial orbits bilaterally. The dura is then cauterized and incised lateral to the tumor. Cortical blood vessels are identified and carefully freed from the dura. The falx is cauterized and transected anteriorly to allow mobilization of the dural specimen. The olfactory bulbs are dissected from the surface of the brain and remain attached to the dural specimen. If there is a focal area of brain invasion, the surrounding cortical tissue is removed by careful and limited suction dissection to achieve clear margins. The olfactory nerves are then transected posteriorly, and the final posterior dural incision is made to free the specimen. Additional dural margins may be excised for frozen section analysis before reconstruction.

After complete resection of the anterior cranial base, an inlay collagen or fascial graft is placed and the septal flap is positioned to cover the defect. If a septal flap is not available because of tumor involvement or insufficient dimension, a modified version of the extracranial pericranial flap is used.¹⁵ A bicoronal scalp incision is made, and the scalp is elevated to the level of the nasal bones. The bone at the level of the nasion is removed with a drill to create a window large enough to transmit the pericranial flap (approximately 1 × 2 cm). The flap is then transposed through the defect inferior to the frontal sinusotomy and positioned over the dural defect, with a drainage pathway for the frontal sinuses maintained on one side.

Approaches to the Middle Cranial Base

Open Approach: Lateral Infratemporal Skull Base Approach

The middle cranial fossa is typically accessed with a lateral transcranial approach. A bicoronal scalp incision is extended laterally in a preauricular skin crease to the inferior margin of the tragus. If transcervical exposure is required, it may be continued into the neck (parotidectomy incision). The scalp is

elevated superficial to the deep temporal fascia to the level of the zygomatic arch.

The lateral approaches to the middle cranial base include the transpterosal approaches, preauricular infratemporal approach, and frontotemporal approach. The frontotemporal (pterional) craniotomy serves as the standard approach to the middle cranial fossa. This approach can be extended with orbitozygomatic osteotomies, depending on the location of the lesion. Orbitozygomatic osteotomies incorporate the superior and lateral parts of the orbit and the zygoma to the standard pterional bone flap, enhancing the low exposure and improving access to the anterior cranial base and parasellar region. Osteotomies are placed across the superior orbital rim, body of the zygoma, and posterior attachment of the zygomatic arch. If exposure of the petrous ICA is necessary, the glenoid fossa can be included with the bone segment. With retraction of the temporalis muscle, a subtemporal craniectomy provides access to the foramen ovale, eustachian tube, and petrous segment of the ICA. This approach also can reach the sphenoid sinus, infratemporal fossa, and pterygopalatine fossa. Bony reconstruction consists of plating of the bone segments and augmentation with titanium mesh. The temporalis muscle covers the craniotomy site, and if dura or petrous ICA is exposed, temporalis muscle can be transposed to protect these tissues.¹⁶

Endoscopic Endonasal Approach: Middle Cranial Base

The endoscopic endonasal approaches permit access to different areas of the middle cranial base: the sella turcica, cavernous sinus, Meckel cave, petrous apex, and infratemporal fossa. Wide exposure of the sphenoid sinus is a common step in each endoscopic endonasal approach to the middle cranial base. Key anatomical structures (optic nerves, internal carotid arteries, cranial nerve V₂, and vidian nerve) are identified within the sphenoid sinus and then followed to other areas of the skull base.

Independently of the area approached in the middle cranial base, the endoscopic endonasal exposure is initiated by lateralization of the inferior and middle turbinates to increase the space for the insertion and manipulation of instruments. The right middle turbinate may be resected to improve visualization of the surgical field. The contralateral middle turbinate is lateralized and the nasoseptal flap is harvested for reconstruction of the cranial base defect at the end of the procedure. The flap can be stored in the nasopharynx or in the ipsilateral maxillary sinus during the operation. A partial posterior nasal septectomy in addition to wide bilateral sphenoidotomies and posterior ethmoidectomies completes the nasal corridor. This corridor provides access to the sellar region and to the cavernous sinus.

The corridor can be expanded laterally by adding a transpterygoid approach to reach the lateral recess of the sphenoid sinus, Meckel cave, and petrous apex. The transpterygoid approach begins with opening of the maxillary sinus and removal of the orbital process of the palatine bone and posterior wall of the maxillary sinus, exposing the pterygopalatine fossa periosteum. Terminal branches of the internal maxillary artery (sphenopalatine, posterior septal, palatovaginal, vidian, and descending palatine arteries) are sacrificed, and the pterygopalatine contents are lateralized to expose the base of the pterygoid plates and the vidian artery in the vidian (pterygoid) canal. The

descending palatine artery and the greater palatine nerve are preserved in the greater palatine canal at the inferomedial margin of the dissection. Once the vidian canal is identified, drilling can then proceed along its inferior and medial aspect. The vidian nerve dissection orients the surgeon toward the lateral portion of the foramen lacerum and the most superficial portion of the petrous ICA.

The transpterygoid approach can be extended to the pterygoid plates. In such cases, the corridor created provides access to the eustachian tube and the infrapetrous region. The infratemporal fossa is approached by removing the posterior wall of the maxillary sinus. This approach provides access to the pterygoid venous plexus, masticator muscles, and cranial nerve V₃ branches.

Approaches to the Posterior Cranial Base

Open Approach: Retrosigmoid Craniotomy

A postauricular incision is made and a subperiosteal flap is elevated. The incision may be extended anteriorly into the upper cervical region for control of the proximal ICA, isolation of the lower cranial nerves, and exposure of the condyle. The upper cervical musculature (sternocleidomastoid and trapezius muscles) is detached from the mastoid and suboccipital region, and a craniotomy is performed posterior to the mastoid and sigmoid sinus. A mastoidectomy with removal of the tip provides greater access to the jugular bulb and foramen.

If a large tumor involves the temporal bone and complete access to the extracranial ICA is needed, a Fisch type C approach provides wide exposure of the middle and posterior cranial fossae. The incision extends from the temporal area to the upper cervical region. A conchal bowl incision through the skin and cartilage allows elevation of the auricle with the skin flap; the stump of the external auditory canal remains. The facial nerve can be transposed for additional exposure or remain in situ. A transtemporal approach is then performed with dissection of the ICA to the carotid canal.

The surgical defect can be reconstructed with temporalis muscle transposition or a posteriorly based pericranial flap (occipital artery). The craniotomy site is covered with titanium mesh or a plate, and the cervical musculature is reattached.

Endonasal Transclival and Transodontoid Approach

The endonasal approach provides optimal access to the clival region from the posterior clinoids to the foramen magnum. A sphenoidotomy is performed, and the mucosa of the nasopharynx and underlying musculature is resected from the floor of the sphenoid to the ring of the C1 vertebra and between the nasopharyngeal eustachian tube orifices. It is important to localize the parapharyngeal ICA with image guidance to avoid injury with dissection or electrocautery. The clivus may be anatomically considered in thirds. The upper third includes the posterior clinoids to the sella floor. Exposure of the posterior clinoids often requires pituitary gland transposition for intradural dissection. The sella is opened widely, and the lateral attachments of the pituitary gland are lysed with possible sacrifice of the inferior hypophysial arteries on one or both sides. If the posterior planum is removed, the gland can be displaced into

the suprasellar space with preservation of the pituitary stalk and the superior hypophysial vessels. The middle clivus extends from the floor of the sella to the floor of the sphenoid sinus. Bone in this area is bounded by the parapharyngeal ICAs, and during drilling the sixth cranial nerve is susceptible to injury posterolateral to the vessels in the Dorello canal.¹⁷ The inferior clivus extends to the foramen magnum. Intense venous bleeding from the clival plexus is often encountered and can be controlled with application of the hemostatic materials of choice, including Surgifoam (Johnson & Johnson, New Brunswick, NJ) and FloSeal (Baxter, Deerfield, IL). The sixth cranial nerve exits the brainstem at the level of the vertebralbasilar junction and is susceptible to injury with opening of the dura (► Fig. 44.4).

If exposure of the upper cervical spine is necessary (basilar invagination, foramen magnum tumor), the anterior ring of C1 is exposed and removed. The odontoid and upper body of C2 can be drilled, and the ligamentous attachments are resected. Laterally, dissection is limited by the vertebral arteries.

Partial-thickness dural defects posterior to the clivus can be simply covered with fibrin glue. Septal mucosal flaps are usually inadequate in size, and reach for large and deep clival or odontoid dural defects and supplementation with fat grafts may be necessary. Pericranial flaps can be used to cover these defects if a vascularized flap is needed.

Endonasal Infrapetrous Approach

The infrapetrous approach is defined by the course of the petrous and parapharyngeal ICA. A lower transclival approach is combined with a transpterygoid approach, and the location of the petrous ICA is defined by using the vidian nerve as a landmark. Bone inferomedial to the pterygoid canal is carefully drilled, and the dense fibrocartilage of the foramen lacerum is exposed. The medial eustachian tube is resected, and the fibrocartilage is transected inferior to the foramen lacerum. This provides access to the inferior aspect of the petrous bone. Lateral dissection is limited by cranial nerve V₃ and the parapharyngeal ICA.

At the level of the foramen magnum, removal of bone laterally exposes the hypoglossal canal and nerve. The bone superior to the hypoglossal nerve is the jugular tubercle and is bounded laterally by the jugular bulb. The occipital condyle is inferior to the hypoglossal nerve; excessive removal of this bone on both sides can destabilize the craniocervical junction.¹⁸

Endoscopic Endonasal Approaches in the Pediatric Population

Specific Considerations

With improvements in instrumentation and the training of skull base teams, the endoscopic endonasal approach to pediatric sinonasal and skull base lesions has become a reality^{19–21} (► Table 44.6). Although the principles of surgery are the same for adult and pediatric patients, pediatric patients may present unique challenges based on the indications for surgery, anatomical access, and skull base reconstruction. It is important to have a skull base team with adequate expertise and experience. This may include both adult and pediatric otolaryngologists and neurosurgeons.

Table 44.6 Lesions treated endoscopically reported in the literature

Disease classification	Pathology
Nonneoplastic	Choanal atresia Rathke cleft cyst Encephalocele Meningocele Cerebrospinal fluid leak Arteriovenous fistula Aneurysmal bone cyst
Neoplasm, benign	Pituitary adenoma Juvenile nasopharyngeal angiofibroma Glioma Epidermoid Olfactory groove schwannoma Teratoma Neurofibroma Ossifying fibroma Osteoma Langerhans cell histiocytosis Hemangioma Leiomyoma
Neoplasm, malignant	Chordoma Craniopharyngioma Germinoma Neuroendocrine tumor Rhabdomyosarcoma Lymphoma

Indications

Applications of endonasal approaches in the pediatric population include biopsy for diagnosis, definitive treatment of benign neoplasms (including pituitary adenoma, angiofibroma, and craniopharyngioma), and downstaging of high-grade malignancies, such as rhabdomyosarcoma. The lesser morbidity and greater acceptance of an endonasal approach lower the threshold for surgical biopsy and provide greater flexibility for the treatment of benign tumors with a propensity for recurrence (craniopharyngiomas). For some benign lesions, there is a role for “wait and watch” until the child is older and more suitable for surgery.

Anatomical Access

Although similar surgical principles apply to adult and pediatric patients, access is limited in smaller patients, and the surgical approach must take into account the potential disruption of growth centers. Despite smaller nares and nasal cavities, most patients older than 4 years have sufficient room for standard endoscopic surgery. If not, a transoral or sublabial approach, such as midfacial degloving in combination with endoscopy, can be used to access the nasal cavity. Incomplete sinus pneumatization in the pediatric population can make the identification of normal anatomical structures more difficult. Cosmetic issues are a concern for both young patients and their parents, and reconstruction options are more limited because of incomplete facial growth and cosmesis. Disparate rates of development between the cranium and facial skeleton decrease the surface area of the nasoseptal flap relative to the anterior cranial base up to approximately 14 years of age.⁶

Blood Loss

The small size of pediatric patients is associated with smaller blood volumes. Hemostasis needs to be meticulous, and intraoperative blood loss is a particular challenge in patients with vascular tumors, bleeding disorders, or a religious aversion to blood products. Strategies to minimize blood loss include preoperative embolization, intraoperative ligation of feeding vessels, and the use of hemostatic materials and instruments. The staging of surgeries is often necessary in such patients to limit the intraoperative blood loss to less than one blood volume at each operation.

Malignant Tumors

Oncologic principles are the same in the pediatric population. The goals of surgery are complete resection of the tumor with the preservation of critical neurovascular structures. The most common malignancies in the pediatric population are sarcomas, and the role of surgery is limited to biopsy and the palliation of symptoms in most cases.

Craniofacial Disruption

A significant concern in pediatric skull base and craniofacial surgery is to avoid disruption of the permanent dentition within the maxillary complex during maxillotomy.²³ Permanent tooth eruption generally occurs after 10 years of age. The Le Fort I down-fracture approach is best avoided, and a presurgical dental panoramic X-ray or coronal CT scan is helpful to plan osteotomies to avoid injury to the tooth buds. With respect to open approaches, midfacial degloving and transmaxillary approaches afford wide exposure and the resection of sinonasal tumors with preservation of normal tooth eruption.

The possibility of skull and craniofacial osteotomies having an impact on the growing head and face is of major importance. A review of patients undergoing craniofacial resection, the youngest of whom was a 2-year-old child, showed normal craniofacial development up to 36 months postoperatively.²³ Longitudinal studies assessing the impact of various external and endonasal approaches on craniofacial growth are needed.

44.6 Specific Skull Base Pathology and Surgical Considerations

44.6.1 Midline Frontonasal Masses

Although they are rare, nasal dermoids, epidermoids, nasal gliomas, and meningoencephaloceles comprise the vast majority of these lesions. Of these, nasal dermoids are the most common, accounting for approximately 61% of congenital midline nasal masses.² The main clinical entities in the differential diagnosis include nasal glioma, encephalocele, and rarely hemangioma, lymphangioma, fibroma, lipoma, lipoblastoma, hairy teratoid polyp, dacrocystocele, and dacrocystitis. A nasal glioma is heterotopic, mature glial tissue (astrocytes and connective tissue) without a true capsule, found within or around the nose. A fibrous stalk representing the intracranial

connection can be found in 15% of cases. Nasal gliomas occur as an extranasal mass along the nasal dorsum in 60%, as an intranasal mass (lateral nasal wall, middle turbinate, nasal septum) in 30%, and in both locations in about 10% of patients.

Surgical resection is the treatment of nasal dermoids and is discussed elsewhere in this text. Although there is very little published literature on endoscopic techniques for the treatment of nasal dermoids, extensive endoscopic experience with lesions in the same area suggests that the same techniques can be applied. Initial experience, including our own, is supportive of endoscopic endonasal surgery for nasal dermoids with intracranial extension.²

Encephaloceles are defects in the skull and dura with herniation of intracranial contents. The most common etiology in children is a developmental anomaly causing the skull defect, and brain tissue (meningoencephalocele) is almost always present. Although rare, congenital meningoencephaloceles are more likely to contain critical vessels or specific neural structures, including the pituitary gland. Acquired defects are most commonly posttraumatic. The surgical treatment of these lesions is covered in detail elsewhere in the text.

44.6.2 Sellar and Parasellar Lesions

The differential diagnosis of pathology in this area includes numerous entities: cystic lesions (Rathke cleft cyst, arachnoid cyst), benign tumors (pituitary adenoma, craniopharyngioma, meningioma, hemangioma, ependymoma), inflammatory and metabolic lesions (hypophysitis, pituitary hyperplasia, fibrous dysplasia, sphenoid sinus mucocele, amyloidosis), and malignancy (pituitary carcinoma, germinoma, chordoma, chondrosarcoma, sinonasal malignancy, osteogenic sarcoma, fibrosarcoma, and metastasis).

Common pathology in this region includes Rathke cleft cysts, pituitary adenomas, and craniopharyngiomas. These lesions have a common embryologic development from primitive stomodaeum (Rathke pouch and duct); however, they differ in pathology and cell of origin (see section on developmental anatomy). The Rathke cleft cyst is a nonneoplastic lesion, whereas pituitary adenomas and craniopharyngiomas are benign neoplasms.

Rathke Cleft Cysts

Rathke cleft cysts can occur in the pediatric population, and it is imperative to distinguish these from cystic pituitary adenomas and craniopharyngiomas. The CT and MR findings are often variable and nonspecific, and it can be difficult to distinguish these lesions. A small, nonenhancing intracystic nodule is considered pathognomonic.³⁶ Most incidentally discovered Rathke cleft cysts are treated conservatively, and treatment is required only in patients who develop clinical symptoms (headache) or demonstrate progressive enlargement. The authors' preferred treatment strategy is via an endoscopic transsphenoidal transsellar/infrasellar approach to fenestrate the cyst and exteriorize the cyst wall. Maximal pituitary gland is preserved by fenestrating the floor of the cyst. Removal of the cyst lining is not necessary and risks a CSF leak.

Pituitary Adenomas

Pituitary adenomas are rare in children and account for 3% of supratentorial masses. They are more likely to be functioning adenomas, in which the most common histology is prolactinoma, followed by corticotropinoma and somatotropinoma.³⁷ Nonfunctioning adenomas, thyroid-stimulating hormone (TSH)-secreting adenomas, and gonadotropin-secreting adenomas constitute 3 to 6% of childhood pituitary adenomas.

Surgery is indicated for almost all histologic types of adenomas with the exception of prolactinoma, which can be successfully managed medically. The preoperative evaluation should include an endocrine work-up, visual field evaluation, and MR imaging with contrast. The goal of surgery is total resection with normalization of the endocrinopathy. An endoscopic endonasal transsellar approach to the pituitary gland achieves complete tumor removal in up to 100% of cases³⁸ with minimum morbidity compared with traditional microscopic transphenoidal approaches.^{38,39} Radiation is avoided in children.

Craniopharyngiomas

Craniopharyngioma is the most common benign pediatric tumor involving the sellar and parasellar region. It comprises up to 50% of sellar tumors and is of epithelial origin. The treatment challenges posed by these tumors are covered separately in the text. The endonasal approach offers a direct, anterior midline surgical pathway to the site of these tumors. Preinfundibular tumors may be removed via a suprasellar, transplanum approach with dissection in a caudal–cranial direction to the supracistern space. Transinfundibular tumors in the subchiasmatic space can be managed via a transsellar approach, and retroinfundibular tumors via a transsellar, pituitary transposition approach with dissection in an anteroposterior angle to the interpeduncular cistern.⁴⁴ However, a significant concern with pituitary transposition is pituitary dysfunction.⁴⁵ In addition, the endonasal approach alone is not suitable for large tumors with extensions beyond the interpeduncular cisterns, and these are best managed with a combined endonasal and open (pterional) or completely open approach.

44.6.3 Fibrous Dysplasia

Fibrous dysplasia is a nonneoplastic condition that results in the intramedullary accumulation of fibrous tissue and immature woven bone in a single (monostotic) or multiple (polyostotic) bones. It is due to an arrest of bone stromal cell differentiation, causing immature cells to proliferate and produce the masses of fibro-osseous tissue characteristic of fibrous dysplasia. McCune-Albright syndrome is a separate condition with several phenotypes and encompasses polyostotic bone involvement, endocrinopathy, and skin discoloration. The natural histories of these conditions are different. Craniofacial involvement occurs almost invariably with the polyostotic form, and the ethmoid bone is most commonly involved, followed by the sphenoid and frontal bones and the parietal, temporal, and occipital bones. Most of the common clinical problems are due to craniofacial asymmetry, pain, and cranial nerve compression. Secondary lesions, depending on the location of fibrous dysplasia, may also be symptomatic: mucocoeles, cystic fibrous dysplasia, hemorrhage, and aneurysmal bone cysts.

In most cases, the diagnosis can be confirmed radiographically.⁴⁶ CT demonstrates an expansile lesion with a fairly homogeneous appearance. There may be hypodense areas or cysts within the lesion. Despite a large mass, the bony growth respects cortical bone and neural foramina; the calvaria is expanded outward, and narrowing of foramina is rare. MR imaging demonstrates low-to-intermediate signal intensity on T1-weighted images and low signal intensity on T2-weighted images, although cartilaginous areas will appear very bright. A common scenario is a child who has MR imaging for unrelated reasons and the doctors are alarmed by a large skull base mass. In such cases, CT is helpful. Biopsy is not necessary to establish a diagnosis if the imaging is consistent with fibrous dysplasia.

Treatment goals depend on several factors. The natural history is an important consideration; it is now evident that fibrous dysplasia can occur after adolescence and progress into adulthood. Polyostotic disease has a higher rate of progression. The rate of malignant transformation (fibrosarcoma, osteosarcoma) is reported to be 0.4%, especially with radiation exposure.⁴⁶ Generally, treatment is reserved for symptomatic patients. Clinical and radiologic follow-up is sufficient, and surgery is considered when disfigurement, cranial neuropathies (including visual loss resulting from optic nerve compression), and pain occur. Although medical treatments with bisphosphonates have been used, the response rate is mixed because of selection bias, and long-term data are lacking. Corticosteroid treatment is reserved for patients with acute visual symptoms before surgery. Headaches do not typically resolve with surgery, and medical therapy should be pursued first.

Surgical intervention is the mainstay of symptomatic fibrous dysplasia. Overall, reports indicate a lower recurrence rate with the complete removal of fibrous dysplasia; however, the extent of surgery depends on the predicted morbidity due to surgery. A useful algorithm for deciding on the extent of surgery, proposed by Chen et al, classifies patients into four major groups according to the area affected: zone 1—fronto-orbital, zygomatic, upper maxillary; zone 2—hair-bearing cranium; zone 3—central cranial base; zone 4—teeth-bearing regions of the maxilla and mandible.⁴⁷ Total resection is suggested for zone 1 and partial resection for zones 2 through 4. Most sinonasal lesions can be completely removed with endoscopic sinus surgery, and skull base lesions are treated with either endoscopic or open approaches (depending on the location and extent of the lesion).

The optic canal is involved in up to 90% of sphenoid bone lesions. Available data indicate that asymptomatic individuals with optic nerve involvement are best managed conservatively, as up to 97% patients had stable vision without surgery.⁴⁶ Surgery carries its own risk for visual deterioration; 87% of asymptomatic patients who underwent prophylactic decompression and 65% of symptomatic patients who underwent surgery had stable long-term vision. If needed, optic nerve decompression can be performed safely with an endoscopic endonasal approach, and partial decompression is often sufficient. Any surgical intervention in patients with fibrous dysplasia is difficult because of the loss of normal anatomical landmarks and risk for neurovascular injury. Surgery should be undertaken by an experienced team with neurophysiologic monitoring and radiologic image guidance.

44.6.4 Paranasal Sinus Mucoceles

A paranasal sinus mucocele is an epithelium-lined sinus cavity filled with mucus secretions that results from obstructed sinus outflow. Its ability to expand by resorption and remodeling of the adjacent bone distinguishes it from a blocked sinus filled with trapped mucus. As it expands, it can erode into the adjacent orbit and skull base. It is rare in children, and predisposing factors include trauma, acute and chronic sinusitis, nasal polyps, cystic fibrosis (with nasal polyps), fibrous dysplasia, and iatrogenic causes (postoperative).⁴⁹ It is important to exclude underlying benign and malignant nasal and sinus lesions, including meningocele, neuroblastoma, lymphoma, and rhabdomyosarcoma. Mucoceles in children are often unilateral and affect the frontoethmoid region, followed by the maxillary sinus, sphenoid sinus, and posterior ethmoid sinus.

The preferred treatment option is intranasal endoscopic surgery and drainage. The wall of the mucocele is removed widely with preservation of the lining mucosa. Recurrence is uncommon and can be further managed endoscopically. Complex cases may have to be managed with a combination of open and endoscopic approaches.

44.6.5 Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma (JNA) is a highly vascular, benign lesion found almost exclusively in males between the ages of 12 and 21 years. JNAs have extensive vascular and fibrous stromal components, and the cells of origin of these components are still debated. Recent evidence indicates that JNA is likely to be a vascular malformation or a hamartoma, derived from incomplete regression of the artery of the first branchial arch, rather than a true neoplasm.⁵⁰ JNA is more prevalent in patients with familial adenomatous polyposis. A hormonal pathogenesis is suggested; however, this remains controversial.

Anatomically, the site of origin lies in an area superior to the sphenopalatine foramen, which some authors consider to be in the pterygopalatine fossa at the level of the vidian canal aperture. The tumor is locally aggressive and from its origin enlarges in a submucosal plane into adjacent anatomical sites and involves the basisphenoid. From the pterygopalatine fossa, it may grow medially (nasal cavity, nasopharynx, and opposite side), anteriorly (toward the maxilla), anterosuperiorly through the inferior orbital fissure (orbital apex), laterally (pterygopalatine fossa to the infratemporal fossa), or posteriorly (root of the pterygoid canal). Intracranial extension is seen in 10 to 20% of patients, and this may occur through direct bone erosion or extension along the pterygoid canal, foramen rotundum, or superior orbital fissure. True dural invasion and intradural disease are rare.

Nasal obstruction and recurrent epistaxis are common presenting symptoms, and in advanced disease, facial deformity can be appreciated. Surgery is the treatment of choice, and CT and MR imaging are useful to delineate the extent of disease for surgical planning. Tumor vascularity poses a significant surgical challenge, and the degree of intraoperative blood loss may influence how much tumor can be resected at any one time. Blood supply is mainly from the internal maxillary artery branches, which can be embolized successfully; however, many intermediate and large tumors derive a significant blood supply

from the ICA (vidian artery and cavernous branches), which precludes effective embolization. Residual vascularity from the ICA is correlated with increased intraoperative blood loss, difficult surgical resection, and the need for multiple surgeries to achieve complete resection. A new staging system based on residual vascular supply has been proposed that provides better prognostication and facilitates preoperative planning.⁵¹

Surgical resection has traditionally been performed via transfacial (lateral rhinotomy, Weber-Ferguson), midface degloving incisions, and, for intracranial components, lateral (pterional craniotomy) approaches. In the past decade, endoscopic transnasal ± transmaxillary (via a Caldwell-Luc) approaches have been used to achieve complete resection of extensive, multi-compartmental, and intracranial lesions. An anterior endoscopic endonasal or endoscopically assisted approach provides access to all routes of tumor extension, both medial and lateral to the cavernous ICA. Incomplete resection of areas of skull base erosion or intracranial extension can be observed for regrowth. Most small residual tumors do not progress and involute over time. In our opinion, there is no role for radiation therapy. Regrowth of residual tumor can be treated endoscopically in most cases. Currently, many authors agree that the vast majority of JNAs, including those with intracranial involvement and significant lateral extension, can be surgically removed without an open approach. ▶ Fig. 44.5 shows a large JNA with intracranial extension that was resected in two stages, including a combined endoscopic and open approach.

Patients should be monitored clinically and with imaging for recurrence. It is generally agreed that surveillance for recurrence can be safely terminated when the patient reaches the early to mid 20s, after the end of adolescence.

44.6.6 Malignant Neoplasms

Malignant neoplasms are uncommon in the pediatric population. A multicenter review of patients younger than 21 years treated for malignancy showed a bimodal age distribution, peaking at 3.5 years and 17.5 years.⁵² High-grade sarcomas (including osteosarcoma, fibrosarcoma, rhabdomyosarcoma, Ewing sarcoma) and squamous cell carcinomas were the most common pathology, followed by esthesioneuroblastoma, low-grade sarcoma, chordoma, and salivary gland malignancy. Histology is the most important predictor of overall survival. A poor prognosis was associated with squamous cell carcinoma and salivary gland malignancies; an intermediate prognosis (60 to 70% 5-year survival) was associated with high-grade sarcoma, esthesioneuroblastoma, and chordoma; and the best prognosis was in low-grade sarcoma. It is interesting that radiation therapy before surgical therapy was associated with a poorer prognosis; however, this must be interpreted with caution because the indications for radiation therapy were not defined, and it is likely that these were tumors considered to be inoperable upon presentation.⁵²

Rhabdomyosarcoma

Sinonasal malignancies are rare in children and constitute a diverse group of pathologies with varying biological behavior. Rhabdomyosarcomas comprised more than 70% of maxillary sinus tumors, and 34% of tumors overall, followed by squamous

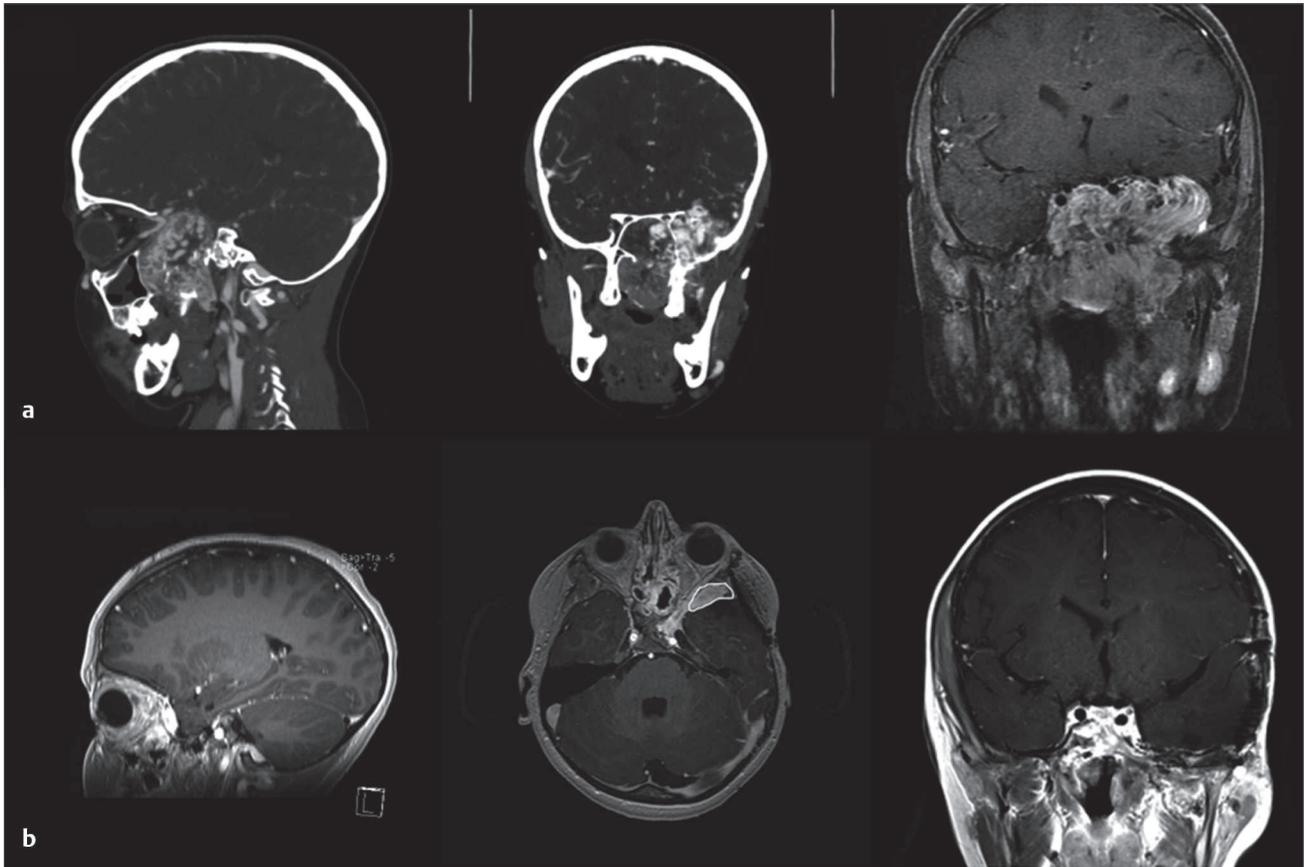

Fig. 44.5 (a) Coronal and sagittal reconstructions from pre-embolization CT angiography and coronal postcontrast T1-weighted imaging of a juvenile nasopharyngeal angiofibroma with intracranial extension that was resected in three stages: a combined pterional and endoscopic endonasal approach and two endoscopic endonasal approaches. (b) Sagittal, axial, and coronal postcontrast T1-weighted images 1 year after resection. On the axial image, a small residual superolateral to the orbit is circled in white. This has remained stable.

cell carcinomas and esthesioneuroblastomas. Rhabdomyosarcomas arise from striated muscle in the head and neck, and more than 50% are diagnosed primarily in the first decade of life. About 40% are located in the head and neck, and these are further divided into three major groups depending on their location: orbital, nonorbital parameningeal (nasal cavity, sinuses, ear, mastoid, pterygopalatine and infratemporal fossae), and nonorbital nonparameningeal (tongue, palate, and other head and neck sites). There are also three major histologic subtypes: embryonal, alveolar, and anaplastic. Tumors in orbital and non-orbital nonparameningeal sites and with embryonal histology (more common in children) have the most favorable prognosis.⁵⁴ Children with tumors in parameningeal sites often present with advanced disease. Overall, the extent of disease at presentation is the best predictor for survival.

A combination of surgery, radiotherapy, and chemotherapy has shown the best survival outcomes for head and neck rhabdomyosarcomas (5-year survival rates of 25 to 83%)⁵⁵ and for paranasal sinus tumors (70%).⁵⁶ The local and regional recurrence rate is reported to be 43%.⁵⁶ Although surgery is considered a valuable treatment in this disease, its role is thought to be limited in those with parameningeal skull base sites because of risks to critical neurovascular structures and morbidity. Endoscopic endonasal approaches can offer a less

morbid option; however, data for surgery at these sites are currently lacking. At present, the role for surgery is in diagnosis, follow-up, and salvage. A recent study showed a prognostic value of debulking surgery, with which the complete response rate was higher.⁵⁷ Orbital tumors have an excellent prognosis with chemoradiotherapy, and the role for surgery is limited to biopsy.

Chordoma

Chordomas are malignant osseous neoplasms arising from remnants of the embryonic notochord and can occur anywhere along the axial skeleton. Three histologic subtypes are described: classic, chondroid, and dedifferentiated. The classic subtype consists of physaliphorous tumor cells with vacuolated cytoplasm, which gives it a “bubbly” appearance, and the chondroid type has features of chordoma and chondrosarcoma. The most common site in children is the skull base, usually the clivus. Chordomas are generally slow-growing, locally aggressive tumors, and metastasis is seen in 10 to 20% of patients, although a rate as high as 43% is reported from autopsy studies. Younger patients can have more aggressive disease, with rapid growth rates and a poor prognosis. Intradural disease is rare. Disseminated disease is a late finding, and control of the primary site is the principal therapeutic goal.

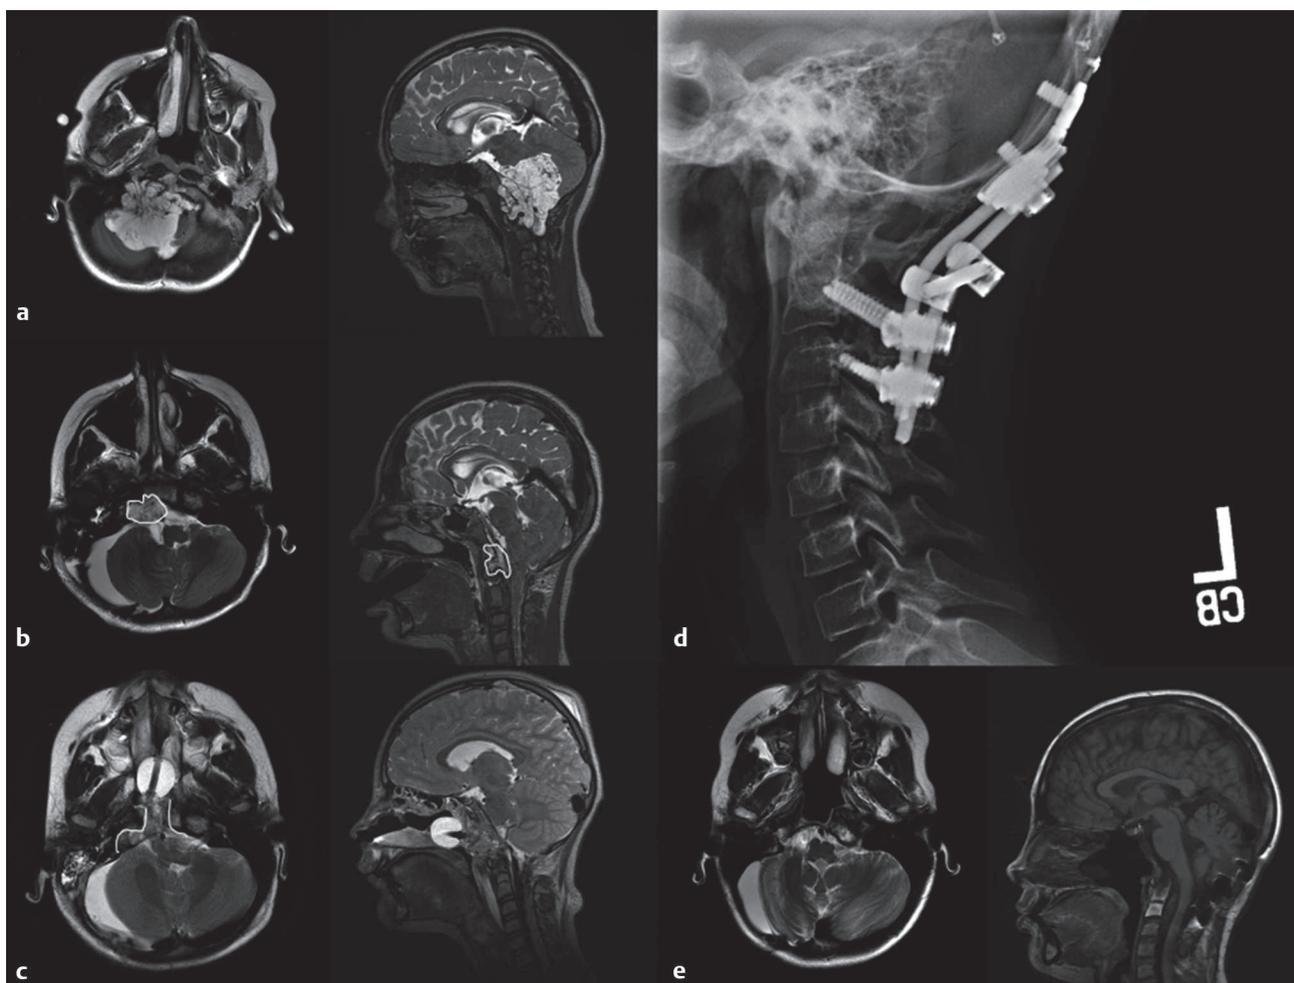

Fig. 44.6 (a) Preoperative axial and sagittal T2-weighted images of a large chordoma. (b) Axial and sagittal T2-weighted images after a far lateral approach. Areas of residual tumor are outlined in white. (c) Axial and sagittal T2-weighted images after an endoscopic endonasal approach for residual tumor involving the clivus and C1–2 joint space. The surgical corridor is outlined in white on the axial image. (d) Occipital cervical fusion was performed after complete resection of the right condyle via far lateral and endoscopic endonasal approaches. (e) Axial T2-weighted image and sagittal FLAIR (fluid-attenuated inversion recovery) image 2 years after resection and proton beam therapy. Radiation changes can be seen in the dens.

Surgery with the goal of complete resection is the primary treatment. The endoscopic endonasal transclival approach is the most direct approach with which to access these tumors. The locally aggressive biology of the tumor makes complete resection a challenge, especially given the close proximity to critical neurovascular structures, including the ICA. Large tumors may require staged surgeries with multiple approaches. ▶ Fig. 44.6 shows a large chordoma resected with a combined open and endonasal approach. Overall average survival is 54% at 5 years, and a worse prognosis is seen in patients younger than 5 years old.⁵⁸ Survival rates were not shown to be significantly different based on the histologic subtype or treatment type (surgery alone or surgery followed by radiotherapy). Radiotherapy is recommended for patients with large tumors and those with less than gross total resection. Diverse radiation treatments have been proposed; proton beam therapy has theoretical advantages compared with standard radiotherapy modalities. In a small retrospective review, the authors proposed a role for chemotherapy (etoposide and ifosfamide) following surgical resection.⁵⁹

44.7 Postoperative Management and Complications

In the immediate postoperative period, antibiotic therapy is continued for 24 hours or until all nasal packing is removed. After endoscopic endonasal procedures with dural reconstruction, nasal packing is maintained for approximately 7 days. Early CT or MR imaging (while the patient is still sedated) is helpful in detecting intracranial complications and assessing the extent of tumor removal. The postoperative management of children is more problematic because of noncompliance with office procedures. Removal of nasal splints and packing, repeated nasal debridement, and imaging studies may require general anesthesia. The management of medical issues such as pituitary dysfunction (hypopituitarism, diabetes insipidus) may delay discharge.

The complications associated with cranial base surgery are myriad and can be life-threatening or trivial, temporary or permanent. There is no standardized classification of skull base complications. A list of possible complications is provided in

Table 44.7 Potential complications of skull base surgery

Category	Incidence	Consequences
Vascular injury (P1 perforator, pontine bleed, internal maxillary artery, frontopolar avulsion, ophthalmic artery, internal carotid artery)	0.9%	Death (0%) Transient deficit (0.1%) Permanent deficit (0.4%) No deficit (0.4%)
Neural injury (cranial nerves III, V ₁ , V ₃ , VI, IX, X, XII; hemiparesis)	1.8%	Permanent deficit (0.5%) Transient deficit (1.3%)
Infection (meningitis, intradural abscess, extradural abscess)	1.9%	Death (0.1%) Deficit (0.1%) Successfully treated (1.6%)
Systemic (pulmonary embolism, pneumonia, myocardial infarction, acute renal failure, respiratory failure, multiple-organ failure)	2.9%	Death (0.7%) Successfully treated (2.1%)
Delayed deficit (visual deficit, hematoma, hemiplegia, ataxia, proptosis)	1.9%	Permanent deficit (0.6%) Transient deficit (1.3%)

Source: Adapted from Kassam AB, Prevedello DM, Carrau RL, et al. Endoscopic endonasal skull base surgery: analysis of complications in the authors' initial 800 patients. *J Neurosurg* 2011;114(6):1544–1568.

► Table 44.7. For the purposes of this review, the more common complications are discussed.

44.7.1 Pituitary: Hypopituitarism, Diabetes Insipidus

Injury to the pituitary gland and loss of function may result from aggressive resection of tumor or loss of blood supply (superior hypophysial vessels). The effects of hypopituitarism will depend on the age of the patient but include cortisol deficiency, hypogonadism, and hypothyroidism. Endocrinologists are involved in the perioperative management of these patients, and hormonal replacement therapy can be instituted. In patients who are at risk for cortisol deficiency, stress steroids are administered perioperatively.

Diabetes insipidus is a consequence of injury to the posterior gland or hypothalamus. It is characterized by a sudden increase in urine output because of impairment in the secretion of antidiuretic hormone. During the postoperative period, urine output of more than 2 to 3 mL/kg for 2 consecutive hours is suggestive of diabetes insipidus. Manifestations include polyuria, dehydration, hypovolemia, and polydipsia. The diagnosis is confirmed if the serum level of sodium exceeds 145 mEq/L, the urine is dilute with a specific gravity of less than 1.005, and the urine osmolality is between 50 and 150 mOsm/kg. The treatment of mild diabetes insipidus includes fluid and electrolyte replacement. The administration of DDAVP (deamino-8-D-arginine vasopressin, desmopressin acetate) is indicated when diabetes insipidus is persistent, dehydration and electrolyte disturbances are severe, or the patient is uncomfortably polydipsic or polyuric. In the postoperative period, diabetes insipidus usually is a self-limited condition, and pharmacologic treatment tends to be temporary.

44.7.2 Cerebrospinal Fluid Leak/Pneumocephalus

A CSF leak occurs in up to 5% of patients undergoing endonasal cranial base surgery and is one of the most frequent major

complications. Risk factors for a CSF leak include patient demographics, patient comorbidities, diagnosis, location and size of dural defect, method of reconstruction, and perioperative management. Younger and older patients appear to be at increased risk, but this may be due to other related factors. Morbidly obese patients have elevated CSF pressures. Similarly, patients presenting with a spontaneous CSF leak and those with significant mixing of blood and CSF have elevated CSF pressures postoperatively. In our experience, patients with craniopharyngiomas have an increased risk for CSF leak that may be a consequence of a high-flow defect as well as transient hydrocephalus from the cyst contents. Large dural defects and those that communicate with CSF cisterns or ventricles pose a greater risk. Successful repair of dural defects has been achieved with a variety of nonvascularized and vascularized tissues. The use of vascularized septal flaps and pericranial flaps has decreased the incidence of postoperative CSF leaks to less than 5%. Although lumbar spinal drainage is often used to treat minor CSF leaks, the routine use of CSF diversion to prevent a postoperative CSF leak has not been convincingly demonstrated.

Usually, a postoperative CSF leak is readily apparent based on the symptoms (unilateral watery rhinorrhea, reservoir sign due to pooling of fluid in the sinuses, "double-ring" sign of blood-tinged drainage) and physical examination (endoscopic findings, Valsalva maneuver). Persistent postoperative pneumocephalus or increasing pneumocephalus implies a dural opening. In questionable cases, a postoperative CSF leak can be confirmed by testing collected fluid for β_2 -transferrin or beta trace protein (although the nasal passages can be contaminated in the immediate postoperative period) or by CT cisternography.

The aggressive management of postoperative CSF leaks is warranted to prevent the sequela of meningitis. For small leaks in the early postoperative period, lumbar spinal drainage can allow the leak to seal. CSF diversion can increase the risk for meningitis, however, because of reversal of flow. Prophylactic antibiotic therapy for CSF leaks is not recommended because of a lack of efficacy and the selection of antibiotic-resistant bacteria. Following endonasal skull base surgery, aggressive management with surgical intervention within 24 hours has been an

effective strategy. Lumbar drains are reserved for recurrent leaks, high-flow leaks, and patients with suspected elevated CSF pressure.

44.7.3 Infection/Meningitis

The incidence of meningitis following cranial base surgery is very low, with reports of 0.9 to 2.5% for transcranial surgery and 1 to 2% for endonasal skull base surgery.^{63–65} Surprisingly, endonasal approaches through a clean-contaminated environment have not been associated with an increased risk for infection. There is no consensus regarding the best regimen for antibiotic prophylaxis, but a single agent with moderate CSF penetration (e.g., a third- or fourth-generation cephalosporin) is sufficient. Factors that contribute to postoperative meningitis include active infection (sinusitis, wound infection), postoperative CSF leak, and the use of nonvascularized tissues for reconstruction. Factors that delay healing (malnutrition, Cushing disease, radiation therapy) may also contribute. Patients with sinusitis should be treated before surgery that transgresses the infected sinus. Early intervention for CSF leaks decreases the risk for delayed meningitis.

44.7.4 Vascular Injury

The risk for a vascular injury depends on multiple factors, including the extent of the pathology, experience of the surgeon, and region of dissection. Injury to small vessels can be as devastating as injury to the ICA. When tumors are dissected from the optic chiasm, the loss of small branches of the superior hypophysial artery can result in visual loss or hypopituitarism. Injury to small perforating vessels when tumors are dissected from the brainstem can result in stroke or hyperphagia syndrome. Tumors of the anterior cranial fossa that encase the anterior cerebral arteries pose a greater risk for dissection. Injury may result in memory and personality changes. Large tumors are internally debulked first to collapse the tumor and allow extracapsular dissection of the tumor margin without retraction. Pulling of tumor is avoided so that small vessels are not avulsed on the backside of the tumor. If tumor cannot be safely dissected from these small vessels, it is better to perform a partial resection.

Injury to the ICA is avoided with a detailed knowledge of skull base anatomy and good surgical technique. Bleeding from the ICA may result from the avulsion of small branches or direct injury. Small arterioles can be sealed with bipolar electrocautery. Larger injuries should be sutured if possible or controlled with the application of a crushed muscle patch. If this is not possible, intraoperative sacrifice of the ICA with packing or placement of aneurysm clips is usually necessary. Postoperative angiography should be performed in all of these patients to detect a pseudoaneurysm. Management includes insertion of a covered stent or angiographic sacrifice of the vessel. The adequacy of collateral cerebral circulation can be assessed with a combination of CT and MR imaging, angiography, and CT perfusion or SPECT (single photon emission computed tomography) balloon occlusion tests. If the collateral circulation is inadequate, a bypass graft from the carotid artery to the middle cerebral artery may be considered.

44.7.5 Neural Injury

Cerebral contusions are a direct consequence of brain retraction, and the surgical approach should be designed to minimize retraction. The incidence of radiographic encephalomalacia is as high as 60% of patients undergoing transcranial surgery of the anterior cranial base. The risk for contusion is increased if there is preoperative cerebral edema secondary to tumor disruption of the blood-brain barrier.

Cranial nerve injury is a consequence of manipulation or ischemia. Surgical approaches should be designed to minimize the manipulation of nerves, and small vessels to the nerves from the cranial circulation should be preserved. The sixth cranial nerve is particularly susceptible to injury because of its long course and small diameter. It can be injured medial (brainstem) or lateral (Dorello canal) to the paraclival segment of the ICA. Neurophysiologic monitoring of the motor component of the cranial nerves and the use of intraoperative nerve stimulation decrease the risk for permanent injury. The sacrifice of cranial nerves is often necessary because of tumor involvement. Care should be taken to avoid loss of the first division of the trigeminal nerve in association with the vidian nerve because the combination of corneal anesthesia and decreased tearing places the cornea at high risk for ulceration. Loss of the vidian nerve is generally well tolerated in young patients (loss of emotional tearing) but may contribute to a dry eye in older patients with decreased baseline tearing.

44.7.6 Craniofacial Growth

The growth of the facial bones lags behind the development of the cranium. Skeletal maturation of the skull shape and size first occurs at the skull base at approximately 12 years, followed by facial maturation at approximately 16 years.⁷ Extensive surgery of the craniofacial skeleton and radiation therapy disrupt growth centers and result in facial asymmetry as the child develops. Surgical approaches should be designed to minimize dissection of periosteum and the disruption of potential growth centers. Endoscopic endonasal surgery may limit the effects of surgery on facial growth, but long-term data on its effects on nasal and midfacial development is lacking. Although nasal septal flaps can be employed for the reconstruction of dural defects in children, they are smaller relative to the anterior cranial base in children younger than 14 years. We have not observed adverse effects on nasal growth, but experience is limited.

44.8 Quality of Life

Studies of postoperative quality of life that use the anterior skull base questionnaire in patients undergoing anterior craniofacial resection for sinonasal malignancy demonstrate good function across all domains.⁶⁶ In patients undergoing endoscopic endonasal surgery of the skull base, excellent quality of life scores are noted when the anterior skull base questionnaire is used.⁶⁷ Limited data suggest that quality of life is superior to that after open transcranial approaches. Nasal morbidity has been assessed in the endonasal surgical group with the Sino-Nasal Outcome Test (SNOT-22), a validated instrument. As expected, increasing nasal morbidity (decreased quality of life)

was noted in the nontranssellar sagittal plane and coronal plane surgical modules compared with transsellar surgery.

44.9 Conclusion

Cranial base surgery is a rapidly evolving subspecialty that requires a vast knowledge of anatomy and encompasses a wide variety of pathologies and surgical approaches. The same principles apply to pediatric and adult populations. Cranial base surgery is best practiced by teams of surgeons with expertise in open and endonasal approaches. Morbidity is acceptable and overall quality of life is good following cranial base surgery. Good oncologic outcomes can be obtained for a variety of benign and malignant neoplasms.

Technological advances will continue to drive advances in pediatric skull base surgery. The increased adoption of minimal access approaches such as endoscopic endonasal surgery requires training programs that provide an incremental and standardized approach to training.⁶⁸ Because of the rarity of skull base pathology, multi-institutional studies of outcomes are necessary to answer basic questions about outcomes and quality of life.

Pearls

- Approaches to skull base tumors should not cross vascular or neural structures.
- Combined approaches should be considered to avoid crossing vascular and neural structures.
- Multidisciplinary teams are beneficial in addressing the varied needs of these challenging cases.
- In young children, a watch and wait approach may be appropriate for benign lesions.
- Minimizing the disruption of growth centers should be considered when planning surgical approaches in young children.
- Skull base reconstruction should be vascularized whenever possible and planned as part of the surgical approach.
- CT-based image guidance can prove invaluable when accessing non-pneumatized sinuses or other cranial base structures in children.
- The embryology and anatomic origin of pediatric skull base and pituitary tumors often makes them most suitable for a midline approach such as the endoscopic endonasal approach.

45 Spinal Extradural Neoplasms and Intradural Extramedullary Neoplasms

Nicholas M. Wetjen, Corey Raffel, and Meghan Murphy

Central nervous system (CNS) tumors are responsible for 24% of cancer-related pediatric fatalities, and 5 to 10% of these tumors arise in the spinal axis.¹⁻³ The ratio of intraspinal tumors to intracranial tumors is smaller in the pediatric than in the adult population, with estimates ranging from 1:5 to 1:20.⁴⁻⁹ Spinal neoplasms may be primary lesions arising within the spinal axis, secondary lesions resulting from extraspinal contiguous spread, or rarely, metastatic lesions.⁴ Neoplasms are categorized according to the space they occupy: extradural, intradural extramedullary, or intramedullary.^{1,2,4}

This chapter features a discussion of the epidemiology, pathology, presentation, and treatment for pediatric extradural and intradural extramedullary neoplasms.

45.1 Epidemiology

Whereas several series show an equal distribution of spinal lesions in boys and girls, others report a predominance in boys.⁵⁻¹³ An increased rate among boys may relate to the inclusion of congenital lesions, which predominate in boys.⁶ Up to 12% of spinal tumors have been reported to arise in the first year of life; these tumors include lipomas, teratomas, and neurenteric cysts.⁴ Neuroblastomas commonly extend to the epidural compartment and cause a mass effect in early childhood, resulting in 12 to 30% of cases of neoplastic cord compression in this age group. Intradural extramedullary spread may occur at any age, although the metastasis of intracranial lesions like medulloblastoma, ependymoma, choroid plexus carcinoma, and retinoblastoma usually occurs within the first decade.⁴ Excluding congenital lesions, tumor occurrence is evenly distributed throughout the first 15 years of life.¹⁴

► Table 45.1 summarizes the various types of neoplasms, both intramedullary and extramedullary, found in the spinal canals of 649 pediatric patients in 10 large series published between 1953 and 1990.^{5-8,10-12,15-17} ► Table 45.2 reviews the anatomical distribution of intraspinal tumors in 413 pediatric patients, with the predominance of tumors arising in the thoracic and lumbar region.⁶⁸ The statistics reported in these large series must be examined carefully, as they often include developmental abnormalities that are not true neoplasms.

► Table 45.2 shows the distribution of tumors, both intramedullary and extramedullary, along the spine. Tumors are distributed fairly evenly throughout the cervical, thoracic, and lumbar spinal regions. The thoracic spine and lumbar spine are the sites of 20.5% and 23%, respectively, of pediatric spinal tumors. This distribution is in contrast to the thoracic predominance of spinal neoplasms seen in adults.⁴ Sacral tumors are less common, and many of the tumors reported to arise in the lumbosacral region may be masses of developmental origin and not true neoplasms.

45.2 Pathology and Pathobiology

45.2.1 Intradural Extramedullary Neoplasms

In adults, tumors in the intradural extramedullary compartment are the most common intraspinal tumors. In children, they account for approximately 25% of intraspinal tumors (► Fig. 45.1 and ► Fig. 45.2). Dermoid and epidermoid tumors comprise about one-third of these lesions, originating in sinus tracts that form during faulty separation of the neuroectoderm from the overlying cutaneous ectoderm at the time of disjunction. Meningiomas are common tumors in adults but account

for fewer than 5% of tumors in children. Although psammomatous meningiomas are the most common type, hypercellular lesions with high mitotic rates occur more often in children than in adults, representing aggressive, sarcomatous lesions.^{18,19} Nerve sheath tumors, such as neurofibromas and schwannomas, account for about 10% of spinal tumors in children and about 30% of intradural extramedullary tumors. Meningiomas and tumors of the nerve sheath are often associated with neurofibromatosis types 1 and 2 (NF-1 and NF-2)²⁰. Myxopapillary ependymomas can also be intradural extramedullary tumors that develop at the filum, enveloping roots in the cauda and/or involving the conus (► Fig. 45.3).

Table 45.2 Levels of intraspinal tumors in 413 pediatric patients

Spinal Level	No. of patients	Percentage (%)

45.2.2 Diffuse Subarachnoid Tumors

The rarest spinal lesions in children are diffuse subarachnoid or leptomeningeal tumors. They usually arise from the dissemination of a posterior fossa tumor along cerebrospinal fluid (CSF) pathways. CSF dissemination most commonly occurs in primitive neuroectodermal tumors (PNETs), germ cell tumors, ependymomas, and malignant gliomas.²¹ These tumors rarely present with spinal symptoms; however, 20% of PNETs in the posterior fossa show dissemination upon presentation.²² Subarachnoid dissemination of an intracranial tumor invariably leads to a poor prognosis.

Histologic grade influences the risk for leptomeningeal metastases in children with primary brain tumors. Civitello et al²³ reported a 2% incidence of leptomeningeal metastases in low-grade gliomas compared with a 33% risk reported in children with supratentorial high-grade gliomas.²⁴ Leukemia is one of the most common systemic malignancies to involve the CNS. Leukemic meningitis may occur either at the time of initial diagnosis (3%) or at the time of leukemic relapse (15%).^{25,26} Surgical approach is indicated only for tissue diagnosis.

45.2.3 Extradural Neoplasms

Thirty-five percent of intraspinal neoplasms in children are extradural. ► Table 45.3 summarizes the extradural pathologies reported in four series.^{15,27–29} Children younger than 3 years of age with an extradural spinal tumor were more likely to have a neuroblastoma/ganglioneuroma (► Fig. 45.4). Sarcoma was more common in patients older than 3 years.¹⁴ Cord compression develops in 3 to 5% of children with a systemic cancer.²

Fig. 45.1 An 11-year-old boy with neurofibromatosis type 2 presented with left leg weakness. (a) T2-weighted- and (b) contrast-enhanced sagittal magnetic resonance images of the cervical and upper thoracic spine exhibit a 2.5 × 3.5-cm homogeneously enhancing lesion ventral to the spinal cord centered at T4. Incidentally, there is also a contrast-enhancing intramedullary lesion at C2. The patient underwent a thoracic laminectomy with resection of this meningioma.

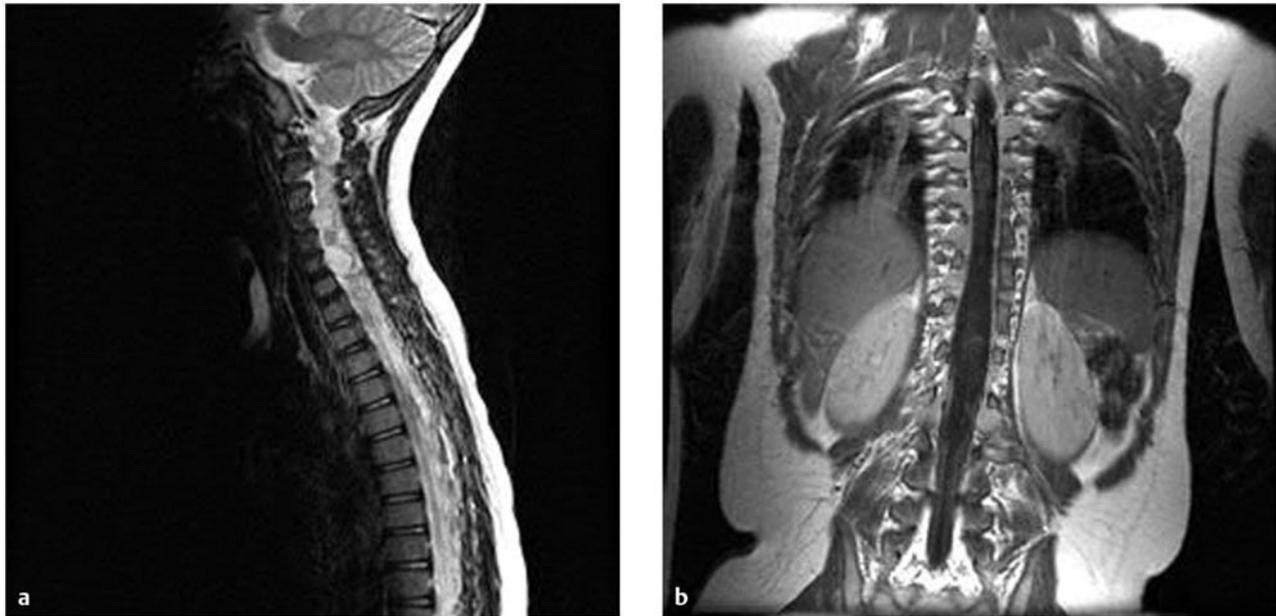

Fig. 45.2 (a) Sagittal and (b) coronal gadolinium-enhanced magnetic resonance images of the cervical and thoracic spine of a 6-year-old girl with neurofibromatosis demonstrate multiple enhancing tumors involving most nerve roots of the cervical and thoracic cord.

45.3 Signs and Symptoms

The clinical manifestations of extramedullary tumors vary with location and the involvement of neural elements and bony structures.³⁰ The onset of symptoms may be rapid, with acute paraplegia and spinal shock, and symptoms presenting for months or years before presentation. The symptoms may also develop following spinal trauma, as a result of increased edema.

In patients with extramedullary spinal tumors, weakness and pain are the most common presenting symptoms (► Table 45.4 and ► Table 45.5). The weakness is usually in the upper motor neuron distribution, with increased tone, hyperactive deep tendon reflexes, and extensor plantar reflexes (Babinski sign). If the conus medullaris or cauda equina is involved, asymmetric, flaccid weakness may occur. In infants and toddlers, the weakness may be subtle; failure to meet gross motor milestones, refusal to walk, irritability, and frequent urinary tract infections may result from spinal cord compression. At presentation, the incidence of weakness was found to range from 53 to 82% depending on the degree of cord compression.^{29,31,32}

Pain occurs most commonly in the back and is reported in 28 to 80% of patients.³¹⁻³³ Distention of the dural tube may cause vague back pain with palpable tenderness. The afferent nociceptive neurons are activated by both the mechanical distortion and the release of inflammatory mediators.^{4,33} Children may have radicular pain radiating into an arm, leg, or the chest wall. Radicular pain can be paroxysmal and spontaneous or provoked by motor or sensory stimuli. Pain with neck flexion or straight leg raise may indicate dural traction, and recumbency may exacerbate pain by altering canal and foramen size.³³ Back or radicular pain in a child with known malignancy requires immediate evaluation. In children without a known malignancy, a careful evaluation is required as to avoid

diagnostic delays.³³ Sensory disturbances are also common in patients with spinal tumors.^{29,31,32} In comparison with pain or temperature, fine touch is a more sensitive indicator of sensory level, although this is not critical with the current noninvasive imaging techniques.⁷

Bladder or bowel dysfunction is also common and occurs in one-half of patients with severe cord compression.²⁹ Changes in bladder function are difficult to detect in young children, especially before toilet training.⁶ Loss of bladder control in a toilet-trained child should raise the suspicion of a spinal lesion. Dysfunction of the bowel or bladder is found only through a careful neurologic examination, and formal urodynamic studies may be merited.

Scoliosis of the spine occurs in about one-fourth of children with spinal tumors and may be the initial presenting sign. In any child with a progressive abnormality of spinal curvature, the diagnosis of intraspinal neoplasia should be considered.^{4,6,7,12,34} Kyphosis is usually a late finding associated with extensive bony metastatic disease.

Patients with spinal tumors, especially malignant tumors, may have hydrocephalus and associated increased intracranial pressure (ICP).^{35,36} Decreased CSF absorption secondary to elevated CSF protein content may lead to hydrocephalus.³³ Patients with spinal cord tumors may have symptoms related to sequelae of their disease: infectious or radiation-related myelopathy, spinal cord stroke, intradural or extradural hematoma secondary to thrombocytopenia or coagulopathy, or an epidural abscess.

The most common nontraumatic acquired cause of paraparesis in children is malignant epidural spinal cord compression by epidural tumor deposits. Cord compression may be the presenting sign of malignancy in 28 to 76% of patients.^{15,27,31,32} These epidural deposits differ from those found in adults in their histologic features, the location and direction of compression, the

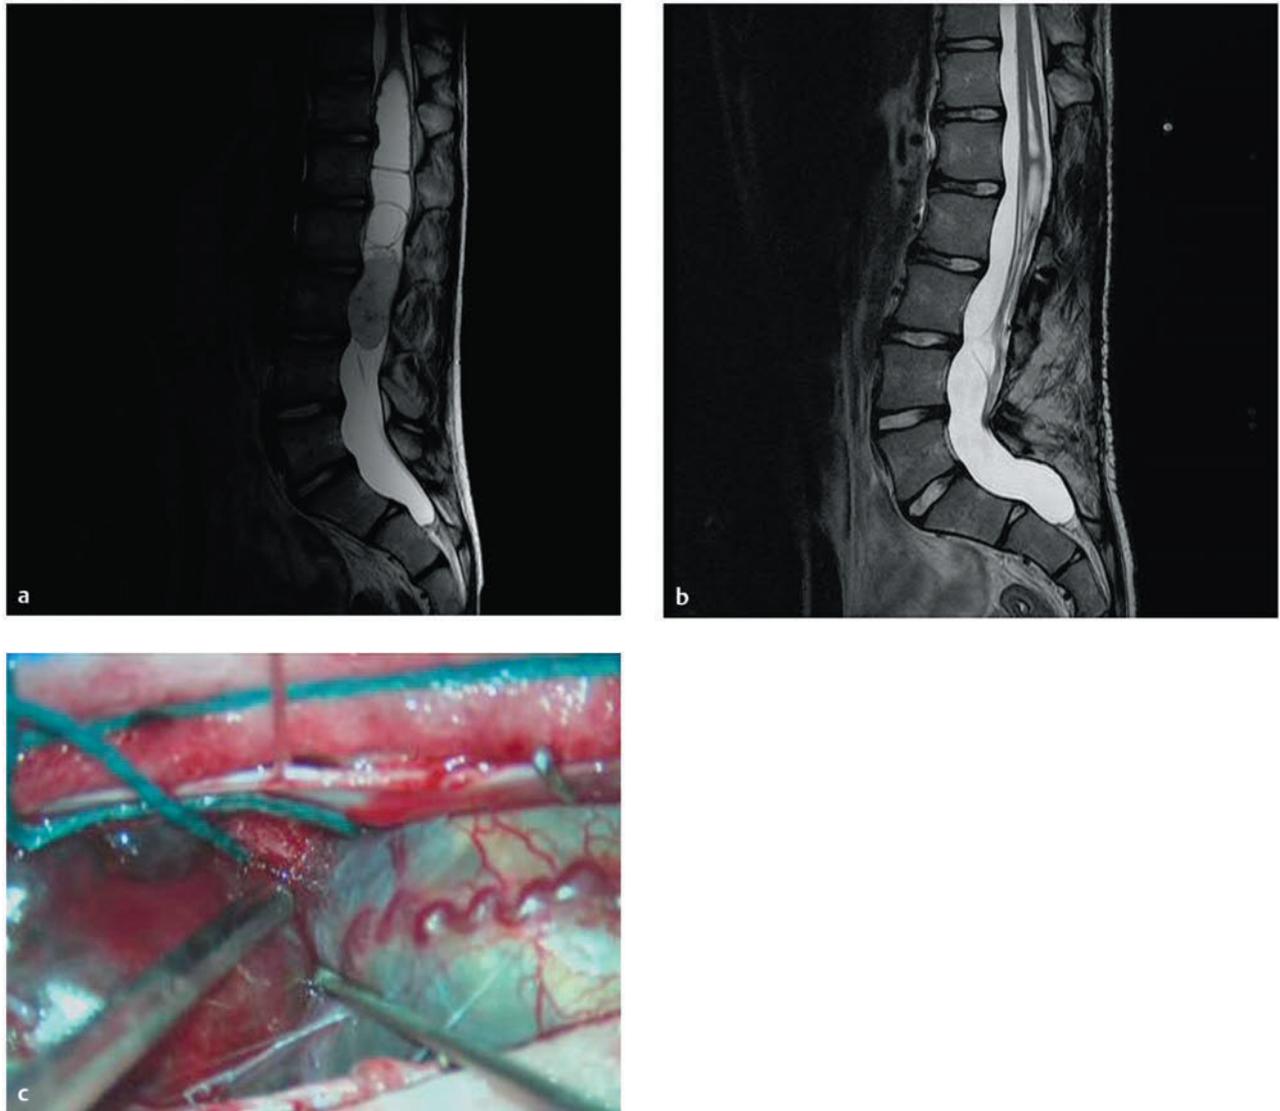

Fig. 45.3 A 14-year-old boy presented with progressive back pain. (a) T2-weighted magnetic resonance image shows a solid mass at the tip of the conus/proximal cauda equina. (b) Image after decompression and gross total resection of a myxopapillary ependymoma. (c) Intraoperative photograph.

degree of bone involved, and the general medical condition of the patient.^{27,31,37,38}

During early childhood, sympathetic tumors such as neuroblastoma and ganglioneuroma predominate. A series reported from St. Jude Children's Research Hospital concluded that 18% of children with Ewing sarcoma, 8% with neuroblastoma, and 7% with osteogenic sarcoma had compression of the spinal cord at some time during their disease.²⁸ In one series, 26% and 21% of cases of cord compression were secondary to neuroblastoma and Ewing sarcoma, respectively.³³ Malignant epidural spinal cord compression is the most frequent neurologic complication of Ewing sarcoma; sarcomas have a higher incidence of spinal cord compression and usually present at a slightly later age.^{27,39}

45.4 Diagnostic Studies

45.4.1 Plain Radiography

Plain radiographs of the spine are a reasonable first step in the evaluation of a patient suspected to have an intraspinal tumor. Plain radiographs show abnormalities in one-half of patients with spinal cord tumors.^{5,16} Intradural extramedullary tumors can thin or cause sclerosis of the pedicles. A tumor that extends through and enlarges a neural foramen is best visualized on oblique films. An enlarged foramen indicates a tumor of the nerve sheath or a paraspinous tumor. Malignant tumors and epidural metastases erode bone and may cause vertebral body collapse. The loss of a pedicle

through bony destruction causes the “winking owl” sign.⁴⁰ Plain radiographs are also important in the evaluation of and surgical planning for patients who present with spinal deformity. They are rarely of value in the evaluation of spinal cord compression. In one series, only 30% of children with metastatic spinal disease presenting with spinal cord compression had abnormal plain radiographs.²⁷ Abnormalities are more often detected in adults with cord compression, in whom most epidural invasion is from vertebral sites versus paraspinous sites in children.

45.4.2 Magnetic Resonance Imaging

Magnetic resonance (MR) imaging is the study of choice to identify spinal cord neoplasms. It provides anatomical detail while obviating the need for lumbar puncture, thus eliminating two risks: (1) bleeding from thrombocytopenia or coagulopathy and (2) acceleration of the rate of neurologic deficit from the loss of CSF. MR imaging is at least as sensitive as myelography combined with computed tomography (CT), providing superior anatomical details in and around the spinal canal.

MR imaging should be performed both with and without intravenous contrast enhancement (gadolinium diethylene-triamine-pentaacetic acid [Gd-DTPA]) and in multiple planes of view. In studies done without contrast, both T1- and T2-weighted images should be obtained. Usually, the surgeon is able to identify abnormal areas in the spinal canal without contrast; however, contrast is useful for defining the extent of tumor.

In a study of patients with documented intradural extramedullary disease, the administration of Gd-DTPA aided in the identification of 2- to 3-mm intradural extramedullary nodules and the demonstration of leptomeningeal spread.⁴ Larger intradural extramedullary lesions, such as nerve sheath tumors and meningiomas, are readily imaged within the subarachnoid space with standard imaging techniques, although the use of Gd-DTPA makes these lesions much more conspicuous and confirms the compartment and extent of the lesion (► Fig. 45.1). Lesions containing fat or cholesterol, such as dermoids, epidermoids, and lipomas, are visualized without the use of contrast.

Intradural extramedullary lesions often displace the cord contralaterally, widening the ipsilateral CSF space and creating

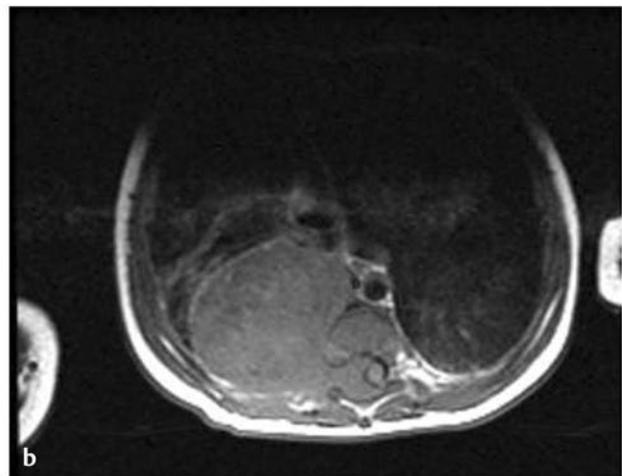

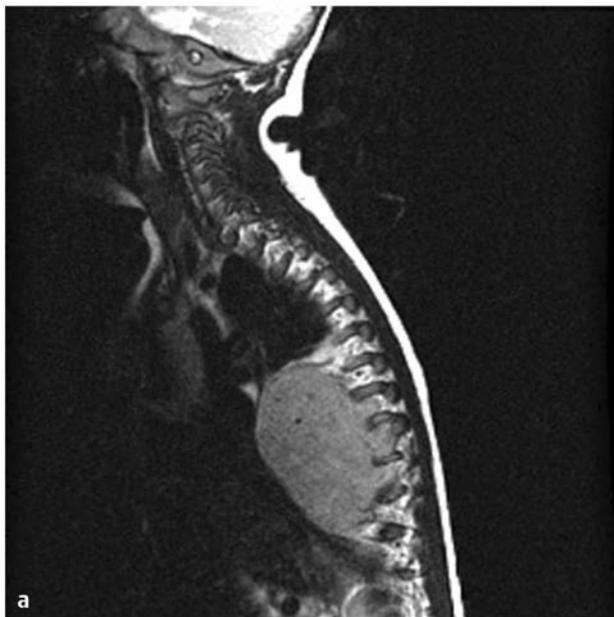

Fig. 45.4 A 5-month-old boy presented with chronic cough. (a) Magnetic resonance imaging demonstrates a large neuroblastoma with extraspinal and intraspinal components. (b) On T1-weighted axial image, the intraspinal component is extradural and compresses the spinal cord laterally to the left.

Table 45.4 Symptoms in 504 pediatric patients with intraspinal tumors

Symptom	No. of patients	Percentage (%)
Weakness	292	54
Back pain	150	30

what is known as the “meniscus” sign.⁴¹ In patients with extradural lesions, T1-weighted images provide adequate tissue contrast. The metastatic deposits are hypointense against the high signal of normal marrow and epidural fat. Metastatic lesions usually have an increased signal on T2-weighted images, but signal characteristics may vary because of hemorrhage, inflammatory debris, and necrosis. Intravenous Gd-DTPA may be helpful, although enhancement may make vertebral and epidural metastatic deposits less conspicuous; the signal is similar to that of normal epidural fat and vertebral marrow on T1 weighted imaging.⁴

Neuroblastomas are usually isointense or hypointense to the spinal cord, and there may be areas of necrosis (► Fig. 45.4). On T2-weighted images, neuroblastoma demonstrates some hyperintensity, and there may be areas of hypointensity secondary to calcification, although rarely. After the administration of Gd-DTPA, there is homogeneous or heterogeneous enhancement.⁴² Neurofibromas and schwannomas can be difficult to differentiate; both are isointense on T1-weighted images and hyperintense on T2-weighted images. Schwannomas may have mixed signal intensity on T2 secondary to different cellular populations, Antoni A and B cells.⁴¹ They may hemorrhage and undergo fatty or cystic degeneration, but rarely do they undergo malignant degeneration. Most neurofibromas are in both the intradural extramedullary and extradural compartments, although a small percentage may be totally extradural. They can be single, multiple, or diffuse (► Fig. 45.2). Neurofibromas can demonstrate a central hypointensity, or “target,” on T2, thought to be a dense collection of collagenous stroma. They may also undergo malignant change.⁴¹ Although usually larger and eroding into bone, neurofibrosarcomas may be difficult to differentiate. Areas of necrosis may become evident with contrast. Once an intraspinal lesion is identified, complete neural axis imaging is warranted to examine for intraspinal dissemination or a primary cranial lesion.²

Table 45.5 Initial signs in 504 pediatric patients with intraspinal tumors

45.4.3 Myelography

Myelography with water-soluble contrast has previously been used extensively in the evaluation of intraspinal lesions in children.^{5,6,12,15,43} However, deterioration after a lumbar puncture has been reported in patients with intraspinal neoplasms,³⁸ and the risk for hematoma exists with coagulopathy in pediatric patients with cancer.²⁹ Myelography should be reserved for patients who require an emergent study when MR imaging is not immediately available.

In intradural extramedullary tumors, the cord is displaced, with a filling defect in the contrast column. Epidural lesions displace both the cord and the subarachnoid space. A complete block of contrast material may prevent a determination of the upper extent of the tumor.

45.4.4 Computed Tomography

CT with intrathecal water-soluble contrast is an important adjunct to myelography.^{12,44} Contrast medium may pass around a high-grade block seen on a myelogram, defining the upper extent of the lesion without the need for a second injection of contrast material. CT with intrathecal contrast is more sensitive than myelography alone in detecting drop metastases and lesions in the epidural space.⁴⁵ High-resolution CT with intravenous contrast may demonstrate whether a tumor, such as a paraspinal neuroblastoma, is in the canal. As well, contrast enhancement can identify the involvement of great vessels with large paraspinal masses.

CT is the optimal study for assessing the degree of bone involvement. The neuroforaminal widening, bone erosion, and vertebral body scalloping caused by neurofibromas and schwannomas are evident on CT. This information is critical for surgical planning.

45.4.5 Ultrasonography

Ultrasonography is of little value in detecting intraspinal lesions because bone is impenetrable to sound waves. However,

a primary lesion can be detected in children up to 3 months of age, when the posterior spinal elements remain largely cartilaginous. Ultrasonography is a valuable intraoperative tool.^{46,47} The thecal sac can be scanned before dural opening to delineate the extent of the tumor. In a comparison of preoperative MR imaging with intraoperative ultrasound, it was found that tumors of the cauda equina can migrate rostrally during positioning.⁴⁸

45.5 Operative Technique

The goals of the operative management of extramedullary tumors are to (1) obtain tissue for histologic diagnosis, (2) preserve neurologic function, (3) treat pain, and (4) maintain or restore spinal stability and load-bearing capacity.³³ The histological diagnosis requires a percutaneous CT-guided or an open biopsy. Open procedures are performed when the initial presentation is with spinal cord compression or when the lesion is too small or dangerous to be sampled percutaneously. The location of the tumor, suspected or prior diagnoses, and the presence of metastatic disease from another known source also direct the choice of tissue sampling.

Corticosteroid use in the preoperative management of patients with extramedullary masses compressing the spinal cord is important for preserving neurologic function. However, no studies have compared type of steroid, route of administration, or duration of therapy. High-dose dexamethasone therapy is most commonly used until the spinal cord is decompressed and neurologic symptoms are improving. Preoperative and postoperative care includes deep venous thrombosis prophylaxis and neurogenic bowel and bladder training regimens.

In adults, spinal cord compression from malignancy is most often caused by the epidural extension of a metastatic lesion into the vertebral body. Thus, the mass compressing the cord is anterior to the spinal cord. This finding led Sundaresan and colleagues^{49,50} to recommend an anterior approach to these lesions, with resection of the vertebral body. Epidural compression in children with malignant tumors is usually caused by direct extension of the tumor through the vertebral foramen without significant involvement of the bone.^{5,10,38,51,52} The mass compressing the cord is lateral to the vertebral body and can easily be reached through the posterior approach. Accessing the tumor with a laminectomy, laminotomy, or transpedicular approach is usually preferred. The goal is an optimal decompression with maximal safe resection. A gross total resection of a malignant tumor is rarely accomplished. However, subtotal removal can be done with minimal morbidity and no mortality.²⁹ Postoperative spinal stability may be an issue, depending on the extent of tumor involvement, resection, and radiation therapy. Most malignant tumors are not vascular and can be removed with conventional microsurgical technique. The ultrasonic aspirator (Cavitron Ultrasonic Aspirator, Tyco Healthcare, Mansfield, MA) can help remove larger lesions. If the tumor invades the dura, the involved area may be resected and reconstructed with a dural graft. Somatosensory and motor evoked potentials may be useful in cases in which the tumor involves nerve roots.²

45.5.1 Intradural Extramedullary Tumors

The treatment of intradural extramedullary tumors is primarily surgical. These tumors are usually nerve sheath tumors or benign meningiomas, which are separated from the surrounding tissue by a distinct margin (► Fig. 45.1). This margin allows total excision in almost all patients. Some nerve sheath tumors extend into the extradural space through the neural foramen, and into the paravertebral soft tissue. A second extraspinal resection may be required to remove the remaining tumor. Careful histologic examination is critical in patients with neurofibromatosis because these tumors may contain malignant elements. Asymptomatic intradural neurofibromas in patients with neurofibromatosis can be clinically followed up with serial MR imaging studies. Surgical removal is recommended for patients with cord compression, intractable pain, or radiographic enlargement.

Dermoid tumors of the spinal canal are most often associated with dermal sinus. The treatment of these tumors is surgical, and the operation is best undertaken before any infection has occurred. Scarring induced by infection makes resection more difficult. If meningitis is present when the sinus is discovered, surgery should be delayed until the infection has been treated. The wall of these tumors is made up of epidermis and dermis. They enlarge slowly, filling with desquamated epithelium, sweat, and sebaceous material. The wall of the tumor may be densely adherent to the conus medullaris or the cauda equina roots, and the tumor may tunnel into the cord. Attempts to remove the tumor wall may result in a significant postoperative deficit; thus, debulking should be the approach. The portion not in contact with neural tissue can then be removed, and the remaining adherent portion can be coagulated or treated with a carbon dioxide laser. Spilling of tumor contents into the subarachnoid space should be avoided because sterile meningitis may occur.² Serial MR imaging is required to monitor for recurrence.

45.5.2 Extradural Tumors

In children, most epidural tumors are extensions of malignant paraspinal neoplasms that infiltrate the spinal canal through neural foramina. The treatment options for malignant tumors in the spinal canal are surgical decompression, radiation therapy, and chemotherapy. Asymptomatic patients with a small intracanal tumor burden or with chemo- or radiosensitive histology should be treated nonsurgically. Considerable controversy exists regarding the best management of intraspinal tumors producing neurologic deficits. Tumor type, extent of spinal cord compression, and deterioration during radiation or chemotherapy all play a role in the management decisions for patients with these tumors. The location, extent of tumor, and previous radiation also play a role in the surgical approach.

45.6 Treatment Alternatives

The multidisciplinary management of children with primary or metastatic spinal neoplasms has become the mainstay of treatment with surgical decompression/maximal resection,

chemotherapy, and/or radiation. Consultations with radiation and medical oncology are necessary to determine a treatment plan, during which chemotherapy protocols and prior treatment are considered and treatment goals are clarified. Pediatric anesthesia, critical care, and rehabilitation are adjuncts available at pediatric cancer centers providing a holistic treatment approach. Treatment plans are affected by the type of tumor, extent of spinal cord compression, and whether a diagnosis has been established. These factors are examined in the next sections with respect to the two most common intraspinal malignant tumors—neuroblastoma and sarcoma. The degree to which surgery, chemotherapy, and radiation play a role in treatment with respect to overall survival and best neurologic outcome has been studied in several clinical trials.

45.6.1 Outcomes

Neuroblastoma

Treatment options for patients with neuroblastoma and spinal involvement include chemotherapy alone, chemotherapy followed by surgical resection of residual radiographic disease, and surgical resection followed by chemotherapy and radiation therapy. In an early series, nine patients with neuroblastoma and evidence of spinal cord compression underwent chemotherapy alone and had successful elimination of tumor bulk, and all patients were able to walk at the completion of treatment.⁵³ In another study treating patients who had dumbbell neuroblastomas initially with chemotherapy, Plantaz et al showed a reduction in the size of the intraspinal mass in 58% and improvement of neurologic deficits in 92%.⁵⁴ Surgical decompression was avoided in 60% of patients. In a series of 112 patients with epidural compression of the spinal cord, Klein et al²⁸ emphasized that the type of tumor is important in the efficacy of nonsurgical therapy. Spinal cord compression from neuroblastoma developed in 32 of their patients; 12 underwent surgical decompression, 16 received only medical treatment, and 3 were not treated because the compression appeared at the end-stage of the disease. No significant difference was seen in the functional outcomes of patients treated surgically or medically. The combined results of the patients with so-called small cell tumors (neuroblastoma, germ cell tumors, and lymphomas) were similar to those for patients with neuroblastoma. Patients without severe spinal cord compression can be treated successfully without surgical decompression. These results have led to the conclusion that surgery is not indicated for asymptomatic children with intraspinal neuroblastoma and other small cell tumors. Massad and associates³⁸ evaluated 80 patients with neuroblastoma admitted to the Beirut Medical Center over a 21-year period. Twelve of these patients had intraspinal involvement sometime during the course of their disease. Intraspinal disease was more common in those patients with mediastinal versus retroperitoneal disease. Only 5% of the 80 patients presented with spinal cord compression, and none had disseminated disease. Patients with intraspinal involvement and less disseminated disease had better survival at 5 years (50% vs. 21%). The factors that affected survival in this study were age, histologic differentiation of the tumor, duration of neurologic symptoms, and mode of therapy.

Prognosis and surgical outcome may also depend on the International Neuroblastoma Staging System (INSS) stage. In a study from Memorial Sloan-Kettering Cancer Center in New York City,⁵⁵ 46 patients with epidural or neural foramina neuroblastoma were stratified retrospectively into high- and low-risk groups according to INSS stage (high risk, 4; n=31; low risk, <4). Patients with normal neurologic examinations regardless of INSS stage had a low risk for neurologic deterioration following surgery or chemotherapy. Patients with high-grade spinal cord compression and neurologic deficits can respond to chemotherapy, but 25% will worsen and may require an operation for progressive neurologic deficits. Chemotherapy may be avoided in low-risk patients who respond to surgery alone. A significant number of patients who underwent operations (30%) developed spinal deformities postoperatively. Most of the operations (34%) were posterior approaches in the lumbar or thoracic segments without instrumentation. Median survival was not significantly different between high-risk patients who did or did not have high-grade spinal cord compression and between patients whose initial treatment was chemotherapy or surgery. This was consistent with the findings in the low-grade groups. There was a trend toward longer survival in the patients without neurologic deficits (5.2 vs. 2.7 years), but it was not statistically significant ($p=0.07$) and may have been due to lower statistical power.

Sarcoma

The experience of Klein et al²⁸ also suggests that some tumors are better treated with surgical resection. In their series of 29 patients with Ewing sarcoma, 20 underwent surgical decompression and 9 were treated medically. The patients in each group were comparable with respect to their neurologic status. Seven of the surgical patients were able to walk independently when they first came for treatment, and all maintained this functional level after treatment. Of the 13 patients who underwent surgery but were not able to walk, all but 1 improved, and 11 were able to walk independently after treatment. Of the 9 patients treated medically, only 3 were able to walk after undergoing treatment. Likewise, of the 14 patients in this series who had rhabdomyosarcoma, all 5 who underwent surgical decompression were able to walk independently afterward. Of the 9 patients treated medically, 1 remained the same and 1 got worse. This series suggests that surgical decompression is the initial treatment of choice for children with sarcomas and compression of the spinal cord.

The degree of compression noted on initial imaging studies may affect outcomes.⁵⁶ The 33 patients in one series had complete or nearly complete blockage on myelography, or the tumor occupied more than 50% of the spinal canal on MR imaging. Twenty-six patients underwent surgical decompression followed by radiation and chemotherapy. At the time of follow-up, 18 of these patients showed neurologic improvement, 7 were unchanged, and 1 was worse. The other 7 patients underwent treatment with radiation and chemotherapy alone. Among these patients, 1 improved and 4 deteriorated while receiving chemotherapy. Surgical outcomes were superior to medical therapy outcomes in an assessment of bowel and bladder function after treatment. This was confirmed in a subgroup of patients from St. Jude Children's Research Hospital who had complete motor and sensory level deficits, recognized

regardless of tumor type.²⁸ In patients who present with cord compression as the first sign of malignancy, surgery is required for diagnosis regardless of the degree of cord compression or tumor type. Surgical therapy is also required in those patients whose condition deteriorates during medical therapy.

Surgical decompression is indicated for patients with severe compression of the spinal cord regardless of tumor type, symptomatic patients with sarcomas, patients with symptomatic compression who have no diagnosis, and patients whose neurologic function deteriorates during nonsurgical therapy. Others can be treated primarily with chemotherapy and radiation therapy.

45.6.2 Complications

Immediate complications of surgical decompression of the spinal cord are rare. These are most commonly postoperative hematomas and wound complications (infection, dehiscence, and CSF fistulas). Reduction of morbidity and mortality in these cases requires careful preoperative planning. Proper positioning of the patient minimizes pressure sores and reduces ventilatory and venous pressures during extensive operations. Anemia from acute blood loss is a common complication, and the preparation of blood products for perioperative transfusion is essential. Maintenance of normothermia lessens the risk for coagulopathy and metabolic acidosis. In the surgical approaches to patients with extradural and intradural extramedullary spinal masses, consideration of en bloc resection is sometimes required for maximal oncologic treatment. This often involves the collaboration of pediatric thoracic and abdominal surgeons to allow a larger surgical field for more complete removal and the placement of stabilizing instrumentation.

Short-term and delayed spinal deformity may occur as a consequence of posterior decompression with laminectomy, with rates varying from 16 to 100% of cases in children, versus 10% of cases in adults.⁵⁷ In an early series of patients with intraspinal tumors treated with laminectomy, cervical kyphosis, anterior subluxation, and disabling scoliosis were observed.^{58,59} Causes of instability may be vertebral erosion, paraspinous denervation or fibrosis, asymmetric irradiation of the spine, or postsurgical destabilization.⁶⁰ This may also be related to a wedging change in the cartilaginous portion of the vertebral body and to the viscoelasticity of ligaments in children.⁶¹ In one series of 31 patients treated for intraspinal tumors, 7 developed a spinal deformity after laminectomy.¹² The incidence of deformity after multilevel laminectomy is related to the patient's age and the spinal level of the laminectomy (► Table 45.6). Reports from the Children's Memorial Hospital, Chicago, Illinois,⁶² suggest that laminotomy is less likely to cause a deformity than laminectomy.^{12,62} After laminectomy, 39% of patients have shown abnormal curvature, whereas 27% have done so after laminotomy. Using a high-speed pneumatic drill, Abbott et al encountered only one technical complication in 180 laminotomies.⁶³ However, other authors have not been convinced of the superiority of the laminotomy.^{55,64} Laminoplasty has also been associated with a high incidence of postoperative deformity; McGirt and colleagues reported similar risks for deformity with laminoplasty and laminectomy after 20 months postoperatively. Laminoplasty has, however, been associated with a reduction in incisional spinal fluid leaks and reduced hospital stay, but further

studies in pediatric populations are required to determine if this association is significant.⁵⁷

One series of 255 children with intramedullary spinal tumors compared the occurrence of postlaminectomy spinal deformity in children who underwent decompression and fusion at the time of surgery with the occurrence of deformity in those who underwent decompression alone. Moderate and severe deformity, defined as scoliosis of more than 25 degrees and/or sagittal imbalance of more than 20 degrees requiring bracing or surgery, developed in 21 of 37 resections (57%) without fusion and in 4 of 15 resections (27%) with fusion. Laminectomy involving laminae at more than three levels demonstrated a significant association with postoperative deformity. Although this series includes only intramedullary tumors, it raises the question of considering postoperative outcomes when a surgical plan is made. For younger patients who have undergone cervical decompression with a multilevel laminectomy, immobilization with a cervical collar is recommended for 3 to 6 months. The first-line treatment for many children with spinal tumors will be a posterior decompression with resection; these patients must be followed closely to monitor for postoperative deformity.⁶⁵

Spinal deformity is also a complication of radiation therapy. Mayfield and colleagues⁶⁰ reported that significant spinal deformities developed in 32 of 57 patients (56%) with neuroblastoma treated with radiation therapy and chemotherapy. A rate as high as 71% has been reported.⁶⁶ A higher rate of deformity is associated with younger age at the time of radiation, doses greater than 20 Gy, and asymmetric radiation fields.^{60,66,67} Radiation-induced myelopathy occurs more frequently at the midthoracic region, the watershed area of the spinal cord. The degree of injury varies with total radiation dose, fraction size, and length and duration of treatment. A threshold for radiotherapy of 45 to 50 Gy has been suggested, delivered in fractions of 1.8 to 2 Gy. With image guidance systems, radiosurgical methods can now be applied to extracranial targets. Mainly used in adult patients with spinal metastases, the concern for posttreatment deformity and radiation-induced myelopathy persists. Further studies are needed to examine the impact on the pediatric population.³⁰

The combination of laminectomy and radiation can pose severe risk for the development of spinal deformity.^{60,66,67} In children who have an epidural tumor without evident cord

compression or neurologic deficit, both surgery and radiation therapy should be avoided. If possible, a child with an epidural tumor should undergo chemotherapy alone. For those patients who require surgery, consideration should be given to bone grafting and/or implants with instrumentation if the degree of tumor or bone removal may result in spinal instability.

Pearls

- CNS tumors are responsible for 24% of cancer-related pediatric fatalities, and 5 to 10% of these tumors arise in the spinal axis.
- In patients with extramedullary spinal tumors, weakness and pain are the most common presenting symptoms.
- Cord compression develops in 3 to 5% of children with a systemic cancer.
- The mass compressing the cord is lateral to the vertebral body and can easily be reached through the posterior approach.
- The multidisciplinary management of children with primary or metastatic spinal neoplasms has become the mainstay of treatment with surgical decompression/maximal resection, chemotherapy, and/or radiation.
- The first-line treatment for many children with spinal tumors will be a posterior decompression with resection; these patients must be followed closely to monitor for postoperative deformity.

46 Intramedullary Spinal Cord Tumors

Mari L. Groves and George Jallo

Primary spinal cord tumors account for approximately 2 to 4% of all central nervous system neoplasms.¹⁻³ The percentage approaches 35% in the pediatric population as well as in young adults,¹ and roughly 100 to 150 cases of pediatric intramedullary spinal cord tumors (IMSCTs) are diagnosed in the United States each year.¹ Ependymomas, astrocytomas, and gangliogliomas account for approximately 80% of IMSCTs.⁴⁻⁸

The development of modern microsurgical techniques, operative equipment, neuroimaging, and intraoperative neurophysiology has elevated aggressive resection of these lesions to the standard of care.^{1,5,6,9,10} As a result, these patients have experienced improvement in long-term survival and quality of life, although late recurrences do occur despite adequate surgical resection. Adjuvant therapy, including radiation and chemotherapy, has resulted in only modest improvement in survival. Tumor location, the patient's age, pathology, and the ability to achieve a gross total resection (GTR) determine whether any adjuvant treatment is necessary.

46.1 Epidemiology

IMSCTs are found throughout the entire neuraxis. In the pediatric population, the majority of these lesions occur in the cervical and cervicothoracic region,^{7,8,11,12} whereas in adults the incidence of intradural extramedullary tumors is increased, and thus the number of lumbar lesions that are diagnosed.⁵ Astrocytomas are the most common IMSCTs found in children^{5,6} but can occur at any age.^{2,7,13} In patients younger than 10 years of age, more than 90% of spinal cord tumors are glial in origin, although this percentage declines to 60% of patients by the adolescent years,^{5,12} with an increased prevalence of ependymomas.

Ependymomas are believed to arise from the ependymal lining of the ventricles and central canal in the brain and spinal cord. There is an association with neurofibromatosis, but most cases are spontaneous. In children, ependymomas are the second most common lesion following astrocytomas and typically occur in the cervical region.^{5,13-15} In children, more than 90% of the tumors are intracranial in origin, and in one series no spinal cord ependymomas were diagnosed in children younger than 3 years of age.¹⁶

46.1.1 Associations with Neurofibromatosis

Neurofibromatosis type 1 (NF-1) and neurofibromatosis type 2 (NF-2) are both associated with tumors of the central nervous

system.¹⁷ NF-1 is an autosomal-dominant disorder with complete penetrance. It has a prevalence of 1 per 3,000. NF-2 is a rarer disease, with a prevalence of 1 per 40,000 people.¹⁸ It is caused by a mutation of the tumor suppressor gene on chromosome 22 called merlin or schwannomin.⁵

Dow and colleagues showed that patients with NF-1 were more likely to present with IMSCTs that were astrocytomas, whereas patients with NF-2 more commonly had IMSCTs that were ependymomas.¹⁹ In the series of Lee and colleagues, the incidence of IMSCT in the total population of patients with neurofibromatosis was 19%.¹⁸ In the series of Malis et al, among 41 patients with NF-2 and 99 spinal tumors, 14 presented with intramedullary tumors.²⁰ NF-2 is more commonly associated with schwannomas and meningiomas, but there is also an association with IMSCTs. Although patients with NF-2 comprise only 0.03% of the population, they are overrepresented among patients who have IMSCTs (2.5%).¹⁸ Additionally, Birch and colleagues showed that 71% of patients with intramedullary ependymomas who did not meet the clinical criteria for NF had mutations in the *NF2* gene²¹ (► Table 46.1).

46.2 Presentation

As in patients with other neuraxis lesions, symptoms depend on the location of the tumor. Most commonly, patients present with pain, followed by gait deterioration, weakness, bowel and/or bladder dysfunction, and sensory disturbance.^{6,10,15} Sensory changes also present differently across the age groups. In young children, localization can be difficult. Their symptoms may manifest only through general irritability or an avoidance of certain positions. Older children sometimes describe a dull, aching, nonspecific type of nocturnal pain. Adolescents may attribute their pain to normal growth and may not present until they demonstrate weakness or an atypical focal finding, such as a subtle change in gait or frequent falling. The pain is typically worse in the supine position as venous congestion distends the dura, causing nocturnal pain. Adults, conversely, will recognize a deterioration of normal function and present with a more classic sensory disturbance.^{15,22}

Children also manifest other typical findings differently from adults. Weakness may be difficult to detect in young children, who are innately clumsy as they are learning to walk. Bowel and bladder dysfunction may also be difficult to detect in infants who are not toilet-trained. However, in a child who has

Table 46.1 Clinical manifestations of neurofibromatosis type 1 and type 2 and associated intramedullary spinal cord tumors

	Neurofibromatosis type 1	Neurofibromatosis type 2
Genetic mutations	von Recklinghausen	merlin, schwannomin
	Chromosome 17	Chromosome 22
Associated intramedullary spinal cord tumors	Astrocytoma	Ependymoma
Other associated central nervous system tumors	Nerve root neurofibromas, optic nerve gliomas, meningiomas	Bilateral acoustic neuromas and schwannomas

Table 46.2 Magnetic resonance imaging characteristics of intramedullary astrocytomas and ependymomas

	Astrocytomas	Ependymomas
Location	Eccentric location Cervicothoracic spine Can extend holocord	Central location Cervical spine
T1	Iso- to hypointense	Iso- to hypointense
T1 with contrast	Heterogeneous contrast enhancement with ill-defined borders	Symmetric contrast enhancement with sharply defined borders
T2	Hyperintense	Hyperintense
Cysts	Less common than with ependymomas except for juvenile pilocytic astrocytomas	Three types of cysts: tumoral cysts from necrosis and hemorrhage, syrinx formation, rostral and caudal cysts from reactive tumor products
Unique findings	Peritumoral edema, more commonly associated with syrinx formation	“Cap” sign, in which areas of low signal density appear on either tumor border that are due to hemosiderin deposits from secondary, chronic hemorrhage

been previously toilet-trained, loss of bowel and bladder control can be a manifestation of an underlying pathology.^{6,10}

Ependymomas, arising from the ependymal cells of the central canal, are well-circumscribed, slow-growing tumors that are centrally located and cause symmetric expansion of the spinal cord.^{5, 23,24} Patients typically present with bilateral dysesthesias at the level of the tumor, as well as paresthesias, radicular pain, bowel and bladder dysfunction, and other sensory disturbances.^{15,22,24} Children commonly present with pain, weakness, gait abnormality, torticollis, or progressive kyphoscoliosis.^{1,6} Hydrocephalus is more commonly found in pediatric patients with spinal cord ependymomas or myxopapillary ependymomas than in those with other IMSCTs and requires shunting occasionally. However, hydrocephalus develops in fewer than 10% of patients, and the etiology is an increased protein content in the cerebrospinal fluid (CSF), arachnoidal fibrosis, and subarachnoid metastasis.^{10,25} Acute decline can follow an intratumoral hemorrhage.²⁴

Patients with IMSCT astrocytomas have symptoms similar to those of patients with ependymomas. Worsening of motor symptoms tends to be earlier in the disease process in these patients than in those with ependymomas. Spinal deformity can be common and presents in up to 30% of patients.^{2,26} High cervical lesions with involvement of the medulla can present with bulbar symptoms, including vomiting, choking, dysphagia, frequent respiratory infections secondary to chronic aspiration, dysarthria, dysphonic speech, and sleep apnea. In younger children, these deficits can manifest as failure to thrive.

46.3 Imaging Characteristics

Magnetic resonance (MR) imaging has dramatically changed the way IMSCTs are evaluated because this is typically the only imaging modality needed to establish the diagnosis. Intramedullary lesions appear as an area of cord expansion on MR imaging and are often associated with cysts or syringomyelia. Tumors may appear isodense on T1-weighted images, and tumoral cysts are hyperintense on T2-weighted images because of the high protein content. The majority of tumors will enhance after gadolinium administration, and differences in enhancement may suggest certain histologies.²⁷ Although a precise histologic diagnosis is not possible via imaging, the lesions do tend to follow typical patterns on imaging²⁷⁻²⁹ (► Table 46.2).

46.4 Differential Diagnosis

Overall, the most common lesions are primary glial tumors. Astrocytomas are the most commonly occurring lesion, followed closely by ependymomas, gangliogliomas, oligodendrogliomas, neurodevelopmental tumors, and malignant gliomas.⁵ Other, nonneoplastic lesions may also occur, such as cavernous malformations and arteriovenous malformations, as well as infectious and inflammatory pathologies.

46.4.1 Astrocytomas

IMSCT astrocytomas arise from transformed astrocytes that then infiltrate the spinal cord. They are histologically identical to intracranial astrocytomas and are graded on the same World Health Organization (WHO) scale: pilocytic lesions (grade I), low-grade astrocytomas (grade II), anaplastic astrocytomas (grade III), and glioblastoma multiforme (grade IV).

Astrocytomas are the most common IMSCTs occurring in children and account for nearly 40 to 60% of lesions.^{1,6,10,15,22} They are the second most common type in adults, with a frequency of 20 to 30%.^{2,5} (► Fig. 46.1). Compared with their intracranial counterparts, they are more benign in presentation and are more commonly low-grade lesions at diagnosis. High-grade astrocytomas comprise 10 to 15% of pediatric spinal cord tumors.^{2,5} They more commonly occur in the cervical and thoracic region in children (► Fig. 46.2). Juvenile pilocytic astrocytomas may be associated with large tumoral cysts; the solid component is often well localized and should be the area that is targeted surgically.^{9,22}

Although genetic alterations are well described for intracranial tumors, very few data exist for spinal cord lesions. However, we assume that there is a correlation because some IMSCT astrocytomas are clustered with inherited syndromes: Li-Fraumeni syndrome, Turcot syndrome, tuberous sclerosis, Maffucci-Ollier disease, and NF.⁵ Although less common than in adult tumors, chromosomal changes in 7, 22, and 10 and molecular alterations of *EGFR*, *PTEN*, and *IDH1* have all been identified in a subset of pediatric gliomas and may contribute to the transition from low-grade to high-grade astrocytoma.^{12,30} However, the genomic changes in most pediatric astrocytomas differ from those in

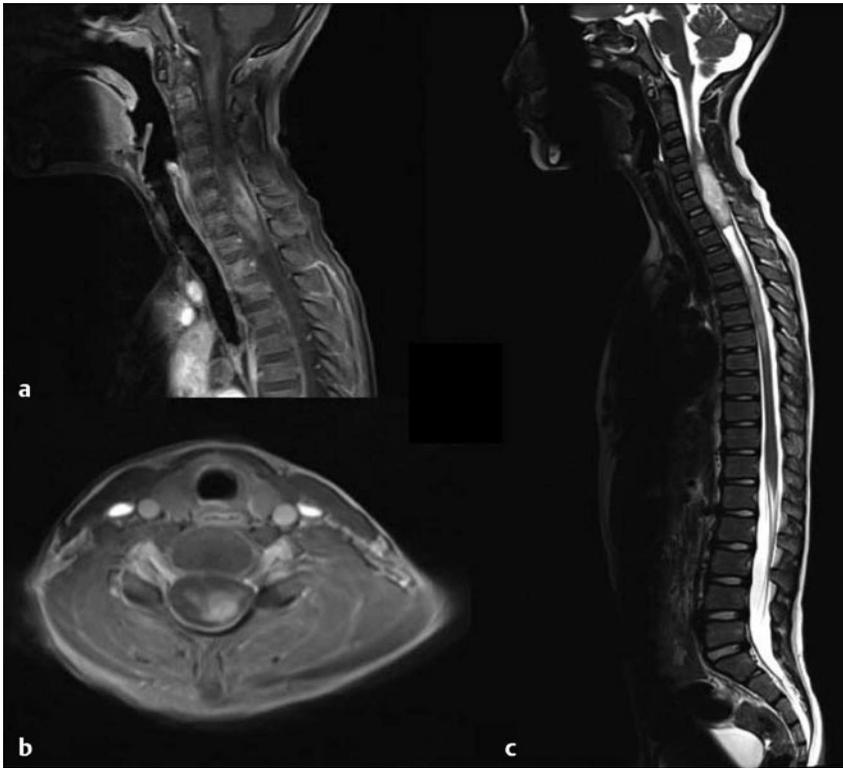

Fig. 46.1 Magnetic resonance imaging in a patient presenting with progressive myelopathy over many months. The histologic diagnosis was World Health Organization grade I astrocytoma. (a) Sagittal T1-weighted image demonstrating heterogeneous enhancement with expansion of the spinal cord. (b) Axial T1-weighted image showing contrast enhancement eccentrically located within the spinal cord. (c) Sagittal T2-weighted axial image showing diffuse hyperintensity with caudal syrinx formation.

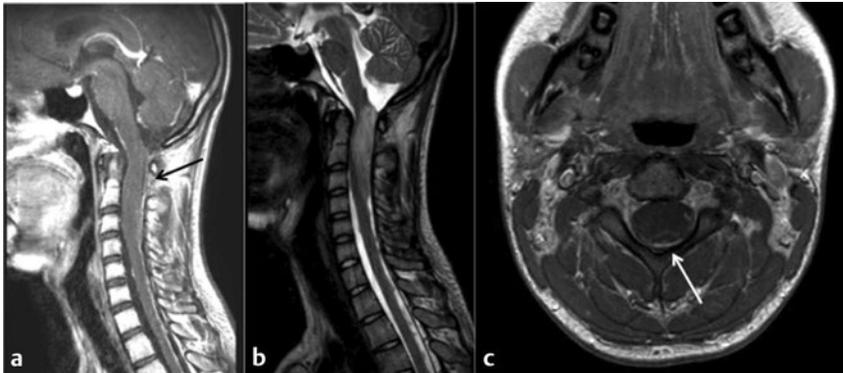

Fig. 46.2 Magnetic resonance imaging in a patient presenting with the acute onset of difficulty walking. The histologic diagnosis was World Health Organization grade IV astrocytoma. (a) Sagittal T1-weighted image shows minimal enhancement of the tumor itself, with the *black arrow* indicating diffuse pial enhancement. (b) Sagittal T2-weighted image showing hyperintensity and edema throughout the cervicomedullary junction. (c) Axial T1-weighted image, with the *white arrow* showing contrast enhancement along the pial border.

adults, suggesting that these tumors may arise from different molecular pathways, which is an area of intense investigation.

46.4.2 Ependymomas

Ependymomas account for 4 to 6% of primary central nervous system tumors, with approximately 30% of these lesions being intraspinal.^{5,12} They can be divided into four subtypes via the WHO classification: subependymoma, myxopapillary ependymoma (grade I), benign or “classic” ependymoma (grade II), and anaplastic ependymoma (grade III). Subependymomas rarely occur in the spinal cord and are mostly intraventricular. Myxopapillary lesions arise from the filum terminale or conus medullaris and are thus found in the lumbar region 20 to 25% of the time, most commonly in adults.¹² Most benign and anaplastic lesions occur in the cervical region. They tend to present in adults between the ages of 30 and 50 years but are the second most com-

mon lesion in the pediatric population (► Fig. 46.3). These tumors are relatively avascular but typically receive their blood supply from branches of the anterior spinal artery, and care should be taken to preserve the normal vasculature during removal.

Approximately 75% of all ependymomas have some chromosomal rearrangement or change.⁵ Mutations of the genes on chromosome 22 associated with NF-2 (merlin) are the most common and occur about 40% of the time. Other chromosomes that have been implicated are chromosome 6 (30.3% of the time), chromosome 9 (27.3% of the time), and chromosome 17^{12,18,19}. The molecular and genetic events that distinguish spinal ependymomas from intracranial ependymomas are more defined than those for spinal and intracranial astrocytomas. Methylation patterns in certain genes, including the tumor suppressor gene *HIC1*, have been implicated in intracranial lesions compared with spinal ependymomas.^{5,12,30} Most recently, Johnson and colleagues have shown distinct genetic signatures for

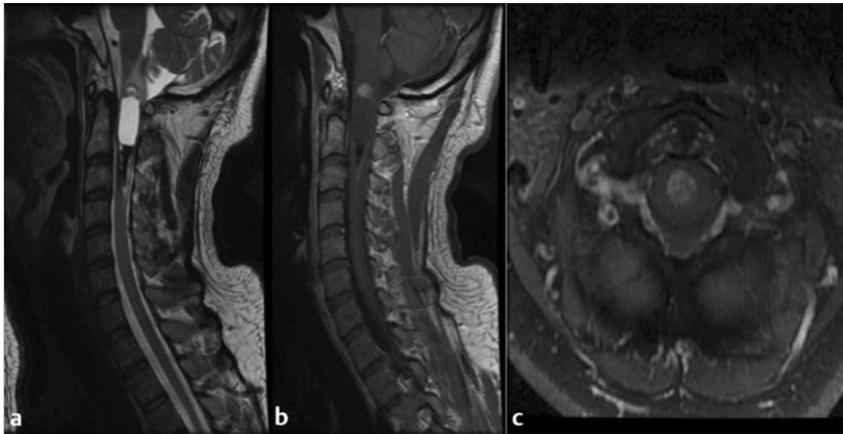

Fig. 46.3 Magnetic resonance imaging in a patient presenting with neck pain over a period of several years who was originally followed conservatively and showed progression. The histologic diagnosis was ependymoma. (a) Sagittal T2-weighted image showing hyperintensity in a central location. Both rostral and caudal cysts show evidence of prior hemorrhage and the classic “cap” sign. (b) Sagittal T1-weighted image shows minimal enhancement of the tumor. (c) Axial T1-weighted image showing central heterogeneous enhancement.

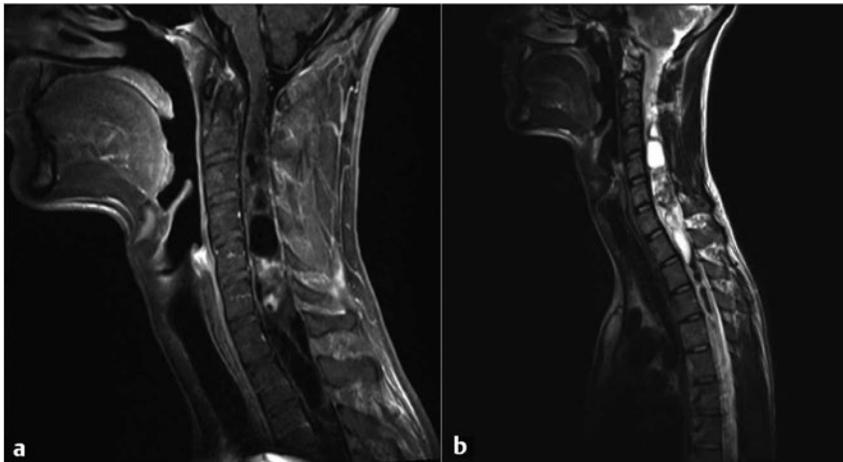

Fig. 46.4 Magnetic resonance imaging in a patient presenting with myelopathy over several years. The histologic diagnosis was ganglioglioma. (a) Sagittal T1-weighted image demonstrating heterogeneous nodular enhancement. (b) Sagittal T2-weighted image demonstrating extensive cystic components both rostral and caudal to the nodular area.

intracranial ependymomas compared with ependymomas originating in the spinal cord. Members of the Notch and Sonic Hedgehog pathways are overexpressed in intracranial ependymomas, whereas overexpression of the Homeobox-containing family of genes (*HOX*) is implicated in spinal cord ependymomas.³¹ These authors have also found that ependymomas are derived from regionally specific stem cells bearing a radial glial cell phenotype.³¹

46.4.3 Gangliogliomas

Gangliogliomas are composed of both neuronal and glial cells. The glial elements are typically astrocytes, and the neoplastic neurons are large and mature in appearance. The frequency of these tumors among IMSCTs has been reported to be as high as 27% in some series,^{11,32} and lesions can be infiltrative (► Fig. 46.4). They are slow-growing and occur in the cervical and upper thoracic spine in an eccentric location. Given their slow growth, they can be associated with bony erosion or scalloping. On imaging, they have areas of mixed signal on T1-weighted images, with heterogeneous enhancement that extends to the surface of the spinal cord, and are associated with prominent tumoral cysts.^{11,32}

46.4.4 Lipomas

Lipomas account for 1% of IMSCTs and arise from embryonal clefts. Although they are commonly thought to be associated with spinal dysraphism, they are indolent in nature, and the presentation is often delayed until adulthood. They are commonly located in the thoracic spinal cord¹² and are histologically identical to normal adipose tissue. They may grow, like any other fatty deposit in the body, and patients may manifest myelopathic signs following spurts of growth or weight gain. Lipomas typically appear as hyperintense lesions on T1-weighted imaging without contrast. Although these lesions are distinct from the spinal cord, they are densely adherent, so that total removal without neurologic deficits is difficult.²⁷

46.4.5 Hemangioblastomas

Hemangioblastomas are relatively rare in the pediatric population, but if found, they are typically associated with von Hippel-Lindau disease.^{5,33} They are located on the dorsal surface of the spinal cord and are associated with large feeding and draining vessels.

46.4.6 Others

Lymphomas and metastatic lesions are more common in the adult population. Lymphomas are rare and are associated with AIDS. They are almost uniformly found in adults. Vascular malformations, including cavernous angiomas, are similar to their intracranial counterparts. They typically present in young adulthood, either with multiple small hemorrhages leading to myelopathy or with an acute hemorrhage that leads to an acute neurologic decline.¹² They account for 1 to 3% of all IMSCTs. Metastatic lesions are also almost always found in adults and can occur from both hematogenous spread and direct leptomeningeal invasion.¹² Other IMSCTs include dermoids, teratomas, oligodendrogliomas, and nonneoplastic lesions, such as sarcooid and multiple sclerosis.

Other intramedullary spinal lesions include inclusion tumors and cysts, nerve sheath tumors, neurocytomas, and melanocytomas. Approximately 4% of IMSCT are found to be non-neoplastic lesions.^{5,12}

46.5 Treatment Strategy

Surgical intervention is the primary treatment of choice for IMSCTs; the goal is complete resection because progression-free survival (PFS) is good when this occurs.^{8,11,13,14,24} Despite multiple trials and retrospective reports, little progress has been made with adjuvant therapy to improve overall survival (OS). Radiation treatment is more widely accepted for patients with incomplete resection and for those with astrocytomas. The clinical benefits of GTR are best established for ependymomas.

The natural history of many IMSCTs is more benign than that of their intracranial counterparts. These patients are often neurologically stable for years with simple observation. However, most surgeons agree that open surgery is indicated because the lesions undoubtedly eventually progress to neurologic deficit.^{5,10,12,22} The outcome for low-grade spinal cord astrocytomas is better in children than in adults, although the prognosis for astrocytoma is not as favorable as that for ependymoma.^{8,10,23,34} Several series have shown that patients with good preoperative function have a better recovery following operation than those with more severe preoperative symptoms.^{7,8,15} One hypothesis is that the spinal cord tissue is more plastic in children than in adults, and this portends a better prognosis.

46.5.1 Surgery

The goal of surgery for low-grade IMSCTs remains GTR with preservation of neurologic function.^{3,8,9} Although the data are more controversial for astrocytomas, several series with data for grade II and grade III lesions have demonstrated an improvement in OS and PFS with aggressive resection of the tumor.^{3,8,22} There are no class I studies for the treatment of IMSCTs.

Maintaining the patient's neurologic function remains an important goal of surgery. Patients with minimal preoperative symptoms have a greater potential for improvement postoperatively. If the tumor is infiltrative, then decompression of the

adjacent spinal cord and the avoidance of neurologic dysfunction should be the goal.^{1,12,23} Closely adherent tumor should not be forcibly removed.⁶ Surgery should ideally occur before the patient has experienced a major neurologic decline because the potential to stabilize or to regain function is limited in these patients.

Astrocytomas are typically eccentrically located several millimeters beneath the dorsal surface of the spinal cord. Radical resection is more controversial because they are infiltrative in nature. However, an excellent prognosis has been reported for patients with low-grade astrocytomas,^{2,7,22} and a radical resection will improve PFS and OS for these patients. These tumors harbor microscopic disease beyond what is visible at the time of surgery, and thus the removal of all cellular atypia is unlikely. Therefore, resection should be continued until the interface between normal spinal cord and tumor tissue becomes difficult to differentiate, so as to minimize the resection of normal neurologic pathways.^{6,8} The tumors are typically resected from the inside out until the glia-tumor interface is identified by the change in color and consistency of adjacent spinal cord. Neuro evoked potentials are critical to guide the extent of resection in the event that motor pathways impede resection.

Like intracranial lesions, high-grade astrocytomas have a poor prognosis, which is not altered by surgical resection.^{1,7,22} Despite resection, they recur rapidly and metastasize throughout the subarachnoid space within a few months. An early biopsy should be taken during surgery if there is any concern for atypia because this will influence how aggressively the tumor will be removed. Evidence of a high-grade lesion, such as a glioblastoma, portends a poor prognosis despite surgical resection. In this case, if there is a cystic component that is causing mass effect, then decompression may lead to some temporary relief of symptoms. However, the patients do poorly and have a median survival of less than 2 years even with adjuvant therapy.

Ependymomas are more distinct from the surrounding spinal cord and have a clear cleavage plane that facilitates resection.¹⁴ They are central in location, and given their cystic nature, the cleavage plane can be further defined at the poles of the tumor. The goal at surgery is to minimize trauma and traction on the normal spinal cord.^{6,9,14} Because PFS correlates with the extent of resection, the surgeon should pursue a GTR.^{5,12,22} However, if the interface between tumor and normal spinal cord becomes indiscernible, then the resection should be halted because neurologic function should be preserved.

46.5.2 Intraoperative Management

Surgical technique is determined by the tumor size and histologic diagnosis at the time of biopsy. A laminoplasty can be performed to expose the extent of the solid component of tumor.⁷ Although laminoplasty has not been definitively shown to reduce the progression of deformity, it has been shown to lower the CSF leakage rate and to help preserve normal anatomical planes.³⁵ If there is concern for the accuracy of the surgical exposure and identification of the tumor, intraoperative ultrasound may be obtained to optimize the size of the laminoplasty, dural opening, and myelotomy. Ultrasonography can also be an important adjunct for identifying the solid and cystic components of the tumor and for determining the depth of resection.

Intraoperative electrophysiologic monitoring is critical to establish the extent of resection during removal of an IMSCT. Somatosensory evoked potentials (SSEPs) measure the afferent conduction of impulses from a peripheral nerve to the brainstem or cerebral cortex. Degradation of the signal results from insult to the sensory pathways, such as the dorsal columns or anterolateral tracts.^{36,37} SSEPs are recorded as an average of many signals, and this can delay the detection of injury. Therefore, motor evoked potentials (MEPs) and epidural electrodes give a better real-time estimate of the integrity of motor pathways. MEPs record a peripheral response to cortical stimulation and are shown as an “all-or-none” interpretation profile. The epidural MEP, or D-wave, measures the direct activation of large-diameter corticospinal axons through stimulation of the spinal cord with an electric current. The amplitude of this signal correlates with the number of intact descending motor units or functioning axons.^{36–38} The epidural electrodes are placed both rostral and caudal to the tumor following the laminectomy.

The intraoperative monitoring of D-waves can make it possible to predict the postoperative functional outcome of patients.³⁸ Both MEP and D-wave monitoring can predict spinal cord damage and transient postoperative effects. If the muscle MEPs are lost but the D-wave is preserved during surgery, then the patient typically has a transient deficit postoperatively. A decrement of 50% in the amplitude of MEPs is an indication to halt surgical resection because this is a measure of a temporary as well as a potentially permanent deficit^{8,36–38} (► Table 46.3). These techniques rely on computer averaging, so there can be a brief delay of 10 to 60 seconds between the time of injury and visualization of a declining response amplitude.

This technology is not without limitations because intraoperative mapping can be influenced by other factors. Anesthetic agents can affect whether nerves can be mapped. Close discussion with the anesthesiologists should be conducted to minimize the intermittent administration of boluses of intravenous anesthetics and of halogenated anesthetics, and to avoid hypothermia. Paralytic agents should also be avoided because they can influence the ability to record MEPs. If the patient has significant weakness preoperatively, the signals can be difficult to obtain and follow.

46.5.3 Deformity

Spinal deformity occurs in conjunction with IMSCTs even if there are no neurologic signs or symptoms. Some children can even present with scoliosis, and up to 37% of children will require stabilization or a brace.¹⁴ This high rate of instability relates to the relative laxity of the ligaments, the horizontal orientation of facet joints, and the dynamic growth of the

osseous spine.^{14,39} Given the low prevalence of instability, prophylactic instrumentation is not used. However, several risk factors are associated with progression to fusion, included age younger than 13 years, involvement of the thoracolumbar junction, tumor-associated syrinx, and preoperative scoliotic deformity^{1,6,7,26} (see box “Predictors of Progressive Spinal Deformity Requiring Fusion after Resection of Intramedullary Spinal Cord Tumors (p.610)”). The incidence of progressive kyphoscoliosis in the thoracic spine and swan neck deformities in the cervical spine is higher in children than in adults.^{7,26} The cervical region is more prone to destabilization than the thoracic or lumbar region. Deformity is also related to the extent of the bony decompression. Radiation and tumor-induced paraspinal muscular weakness further destabilize the body’s ability to compensate for bony loss.^{26,39}

Predictors of Progressive Spinal Deformity Requiring Fusion after Resection of Intramedullary Spinal Cord Tumors

Predictors of progressive spinal deformity requiring fusion:

- Age younger than 13 years
- Symptoms for less than 1 month
- Preoperative scoliosis
- Thoracolumbar involvement
- Syrinx (on preoperative magnetic resonance imaging)
- Higher total number of operations

Adapted from Yao KC, McGirt MJ, Chaichana KL, Constantini S, Jallo GI. Risk factors for progressive spinal deformity following resection of intramedullary spinal cord tumors in children: an analysis of 161 consecutive cases. *J Neurosurg* 2007;107(6 Suppl):465.⁴⁴

There is controversy regarding the need for spinal fusion at the time of surgery to prevent progressive deformity after IMSCT resection. In a review of 33 patients, Simon et al found that 25% of patients who underwent fusion at the time of tumor resection progressed to significant spinal deformity, compared with 62% of patients who underwent laminectomy and laminoplasty alone.³⁹ External orthotic bracing is also an option to prevent postoperative spinal deformities. However, this is sometimes not comfortable and can lead to social stigma in young children, although it is otherwise well tolerated. We typically recommend preoperative X-rays so that these children can be followed with serial imaging studies.

46.5.4 Radiation

Radiation treatment has been limited to instances of incomplete resection and malignant tumors.⁴⁰ Radiation has

Table 46.3 Interpretation of motor evoked potentials during intramedullary spinal cord resection

D-wave ^a	Muscle motor evoked potential ^b	Postoperative motor status
Decreased <50%	Unchanged	Unchanged
Decreased <50%	Unilateral or bilateral loss	Transient motor deficit
Decreased >50%	Bilateral loss	Prolonged motor deficit

^aD-wave measures the direct activation of large-diameter corticospinal axons through direct stimulation of the spinal cord by an epidural electrode.

^bMuscle motor evoked potentials measure the peripheral response to cortical stimulation as an “all-or-none” interpretation.

deleterious effects on the vertebral column and increases the risk for secondary neoplasms many years later. For this reason, there is growing consensus to delay radiation treatment as long as possible in the pediatric population.¹²

Radiation for low-grade ependymomas remains controversial. Multiple series show that long-term tumor control is better with GTR than with subtotal resection and radiation.^{5,9,12} Most centers do not recommend radiation treatment if GTR is obtained, despite a risk for recurrence of 5 to 10% at 10 years.⁴⁰ For patients in whom a GTR cannot be obtained, postoperative radiation is based on small studies with limited follow-up.⁴⁰ However, most studies show some benefit for radiation following subtotal resection of an ependymoma.⁴⁰ Some centers will advocate reoperation and another attempt at resection at the time of recurrence before radiation.^{23,40}

For astrocytomas, GTR is not often achieved, and radiation is less controversial. Many still advocate monitoring with serial MR imaging and reoperating if there is concern for regrowth and worsening symptoms because the natural history of these lesions is indolent. However, other authors have shown some improvement in survival with adjuvant radiation. Patients with malignant astrocytomas typically undergo total neuraxis radiation and chemotherapy, although this has shown to have limited efficacy in achieving long-term survival.

The typical dose is 5,000 to 5,500 cGy delivered in fractions of 180 to 200 cGy with external beam radiation. The lesion is typically radiated only at the area of focal disease because most recurrences are local and do not disseminate.⁴⁰ For young children, the overall radiation dose is lowered by at least 1,000 cGy because they are more susceptible to the adverse effects of radiation. Craniospinal radiation is rarely warranted for low-grade lesions and is indicated only when there is multifocal disease that is not amenable to GTR.⁴⁰

46.5.5 Chemotherapy

The role of chemotherapy has not been clearly defined in the treatment of IMSCTs. Despite the widespread use of chemotherapy for intracranial lesions, the improvement in outcome for patients with spinal cord lesions has not been as definitive. The guidelines for pediatric IMSCTs have been extrapolated from our clinical experience with intracranial ependymomas and low-grade astrocytomas.⁴¹ No randomized clinical trials have been performed, and most series are limited, with small numbers of intramedullary spinal lesions. However, given the desire to delay or avoid radiation therapy in young children, adjuvant chemotherapy plays a role in delaying radiation.

Multiple drugs have been studied as treatment for supratentorial ependymomas. Platinum-based regimens in conjunction with nitrosourea-based regimens have shown some promise.⁴¹ Etoposide, a topoisomerase II inhibitor, has also been used to treat recurrent intramedullary ependymomas and is apparently well tolerated. Two recent reports of pediatric IMSCT astrocytomas demonstrated adequate results, showing a potential to target these tissues and improve patient survival.⁴¹

46.6 Outcome

Patient outcomes are influenced by three major factors: histologic grade of the tumor, preoperative functional status,

and surgical resection. The histologic grade often correlates with the degree of invasiveness and the possibility to obtain a GTR. Children with low-grade astrocytomas can have a survival of 60 to 80% at 5 years. Children with juvenile pilocytic astrocytomas have a better prognosis than those with diffuse fibrillary astrocytomas.²⁵ Malignant astrocytomas have a poor prognosis despite extensive resection. Most low-grade ependymomas have a high likelihood of being completely resected. Higher-grade ependymomas are scarce among intramedullary spinal lesions. Low-grade astrocytomas are biologically more indolent than their intracranial counterparts in both adults and children.

As discussed previously, surgical resection is an important predictor of outcome and long-term survival for any type of low-grade lesion. OS and PFS in patients with high-grade lesions have not been altered despite aggressive resection. Several series have shown a survival benefit with resection of more than 95% of tumor across all low-grade glial tumors.^{6,15,22} GTR is often more likely to be accomplished for ependymomas than for astrocytomas. Despite GTR, late recurrences can occur, even 12 years following surgery. Local control rates can be 90 to 100% with surgery even if GTR cannot be accomplished. Overall, patients with ependymomas have prolonged PFS and OS, with a median of 82 and 180 months, respectively.^{5,12,14}

Postoperative functional outcome is most strongly tied to preoperative functional ability.^{7,12,23,42} Despite a successful surgical excision, a severe or long-standing preoperative deficit is unlikely to show any improvement.^{5,7} Surgical morbidity is also more significant in those patients with preoperative deficits.^{5,7}

The most common neurologic dysfunction following surgery is dorsal column dysfunction. Despite this difficulty, most patients are able to ambulate independently within a few months.⁷ Other sensory deficits improve over a 3-month period.^{7,22} Additional morbidity is related to the location of the tumor and spinal cord atrophy. Thoracic lesions have been associated with a higher likelihood of decline, perhaps because of a more tenuous blood supply.²³

Age is also associated with the likelihood of postoperative recovery. Postoperative neurologic function was improved or stable in 75 to 90% of adolescent patients.^{7,15,23} These patients also had a faster improvement in neurologic function immediately following surgery than comparable adults did. In younger patients with postoperative deterioration, recovery and normalization were seen as early as 2 to 6 months.⁵ Conversely, adults were more likely to have a prolonged recovery with a higher likelihood of permanent deficits.

46.7 Future Studies

GTR will remain the first-line therapy for low-grade IMSCTs. However, adequate adjuvant therapy has continued to be more elusive for these lesions than for their intracranial counterparts. Despite an indolent course, the lesions do progress and eventually lead to neurologic decline and severe morbidity. Although radiation can provide some symptomatic relief and perhaps a delay in symptoms, it may not produce a definitive halt in disease progression. Future therapies will likely concentrate on targeting complementary or synergistic antitumoral agents at these low-grade lesions. Chemotherapy does not play a role in OS, likely because the blood-brain barrier interferes with the

access of systemically administered therapies to the spinal cord. These lesions grow slowly, so that conventional chemotherapy and radiation, which target rapid cellular turnover and angiogenesis, may not be the best agents for treating low-grade lesions. As we better understand the genetics and epigenetics that make these IMSCTs unique, we will undoubtedly find better targets for adjuvant therapy. Local delivery within the tumor bed has shown some promise; injection of a gel embedded with chemotherapeutic agents into an IMSCT achieved an improvement in median survival and improved functional motor scores in a murine model.⁴³ However, whether this therapeutic option will have any efficacy in treating human IMSCTs remains to be seen.

46.8 Conclusion

IMSCTs remain challenging lesions, but significant advances have been made over the past several decades. Modern microsurgical advances and the advent of MR imaging have made it possible to classify these lesions and improve OS. In children, IMSCTs are typically low-grade lesions and have an indolent natural history. They are most commonly low-grade astrocytomas, and adjuvant radiation and chemotherapy have not made a significant impact on PFS or OS.

Current standards of care include surgery with GTR for ependymomas and attempted GTR for low-grade astrocytomas. Surgical resection should continue as long as a cleavage plane exists and there is minimal adherence to normal neural tissue. If postoperative MR imaging demonstrates unexpected residual tumor, the patient should undergo a second-look operation to achieve maximum resection. Osteoplastic laminoplasty should be used to decrease postoperative CSF leaks and prevent spinal deformity. If a GTR is achieved, then radiation therapy should be withheld. Current guidelines include holding radiation therapy if radical or total resection of low-grade astrocytomas is achieved. Intraoperative ultrasonography, SSEPs, and MEPs should be used to guide the extent of resection. Patients with malignant astrocytomas should undergo limited resection with postoperative irradiation.

Surgery should be considered first-line therapy for these patients. Neurologic improvement following surgery is unlikely unless the preoperative deficits are due to mass effect from an intratumoral cyst or syrinx. However, across all ages, children have the best potential for improvement in neurologic function postoperatively. GTR has been shown to provide patients with the best chance of PFS and OS. This is more easily accomplished for ependymomas and hemangioblastomas if there is a clear intraoperative tumor plane. Low-grade astrocytomas and ganglioneuromas are more infiltrative in nature and can be difficult to resect completely. Intraoperative electrophysiologic monitoring can provide a guide for resection because if the amplitude of the MEPs falls below 50% of baseline, this can indicate permanent damage to the motor pathways. Despite GTR, disease will recur in some patients, and adjuvant therapies are limited. Chemotherapy has not proved useful in most cases, and targeted therapy and improved drug delivery will be important avenues of exploration to improve upon surgical outcomes.

Pearls

- GTR is associated with improved outcomes overall, although this is less likely to be achieved for astrocytomas than for ependymomas.
- Adjuvant therapy plays a minimal role in the treatment of most IMSCTs. High-grade lesions have been treated with radiation therapy, but results continue to be disappointing in terms of PFS and overall survival. Chemotherapy may have some utility in the attempt to delay radiation therapy for young patients. However, studies have not shown significant improvements in survival or PFS compared with the natural history of the disease process for most patients.
- Intraoperative monitoring plays a critical role in the resection of IMSCTs. A decrement of greater than 50% in D-waves in addition to muscle MEPs signals a prolonged motor deficit, and the goal is to halt the resection before this loss of signal.
- Spinal fusion at the time of resection should be considered in patients who are at high risk for postoperative deformity. However, we tend to avoid simultaneous procedures because the hardware may interfere with MR imaging. We prefer to follow patients with serial X-rays.
- Recurrences of low-grade astrocytomas and ependymomas in patients who are ambulatory and have good neurologic function should be treated with reoperation and tumor debulking.

47 Spine Tumors

David H. Harter and Howard L. Weiner

The classification of spinal tumors is based on their anatomical origin and extension, specifically with relation to the spinal cord (intra- or extramedullary) and dura (extra- or intradural). This chapter focuses exclusively on pediatric extradural tumors involving the spinal column. These tumors may arise from osseous or paravertebral structures and may be primary or metastatic. Spinal column tumors are rare in children and young adults, accounting for fewer than 1% of all spine and spinal cord tumors combined. The clinical symptoms, usually pain, allow early diagnostic consideration and evaluation. This chapter focuses on the more commonly encountered benign and malignant conditions, with an emphasis on diagnostic and treatment paradigms.

47.1 Epidemiology

Considered as a group, intramedullary, intradural extramedullary, and extradural spinal tumors account for 5 to 10% of all pediatric tumors of the central nervous system. Extradural primary or metastatic tumors account for approximately 50% of cases, followed by intradural intramedullary tumors (40%) and intradural extramedullary tumors (10%).¹⁻³ By comparison, pediatric brain tumors are six to seven times more common than pediatric spinal tumors. Extradural tumors are equally distributed throughout the mobile spine; sacral involvement is less common, except in the case of giant cell tumors and chordomas.

The primary tumors emphasized in this chapter include osseous tumors (osteoid osteoma, osteoblastoma, osteochondroma and osteogenic sarcoma, aneurysmal bone cyst [ABC], and eosinophilic granuloma). Malignant tumors (neuroblastoma, Ewing sarcoma, rhabdomyosarcoma, and chordoma) and metastatic tumors are also included here.

47.2 Clinical Symptoms

Spinal tumors in children may present with symptoms due to osseous or neural involvement, which causes pain, neurologic deficit, and/or spinal deformity. Most commonly, pediatric patients present with axial or radicular pain. The onset of symptoms may be acute in the case of vertebral collapse or epidural spinal cord compression. Slow-growing tumors may result in an insidious progression of symptoms. Persistent back pain, particularly when nocturnal, in a child should prompt diagnostic evaluation.⁴⁻⁶

The symptoms of spinal tumors in children are age- and location-dependent. Tumors causing compression of the spinal cord may produce upper motor neuron signs: weakness, hyperreflexia, hyperreflexia, clonus, Babinski sign, and sensory deficits. Lower motor neuron findings, including weakness, hypotonia, hyporeflexia, and sphincter dysfunction, may predominate in children with tumors involving the lumbar and sacral segments. The presentation of spinal tumors in infants and toddlers may be subtle, with irritability and regression of motor milestones.⁵

Spinal deformity, including kyphosis, scoliosis, and lordosis, occurs in up to 25% of children with spinal tumors and rarely is the sole presenting sign of a spinal tumor.^{5,7,8} The severity of spinal deformity generally relates to the extent of osseous destruction and neurologic deficit, although occasionally, a small tumor may cause a significant deformity.^{4,5,9} Spinal deformity may also develop after the treatment of spinal tumors; multilevel laminectomy and radiation therapy significantly increase the risk for deformity.^{10,11}

47.3 Diagnostic Imaging

Modern imaging permits a detailed anatomical visualization of the spinal and paravertebral structures, often allowing an accurate and concise differential diagnosis. Plain radiographs, often the initial study, can identify lytic or blastic lesions with a high rate of sensitivity.⁸ Additionally, spinal alignment can be assessed and the degree of scoliosis, if present, quantified.^{8,9} Computed tomography (CT) provides further detail and may reveal abnormalities not demonstrated on plain radiographs. Three-dimensional reconstruction of CT scans may also be useful for surgical planning. Magnetic resonance (MR) imaging adds anatomical detail of soft tissue and neural structures, demonstrating edema or compression of the spinal cord or nerve roots. Technetium bone scan may be helpful in selected cases, particularly when symptoms persist and the results of alternative imaging modalities are negative or equivocal.^{12,13} Spinal angiography is rarely indicated, although endovascular interventional techniques may be an important adjunct in the treatment of highly vascular lesions, such as ABCs and giant cell tumors.¹⁴⁻¹⁷

47.4 Treatment

The goals of treatment of spinal tumors are histologic diagnosis, complete tumor removal, and improvement or preservation of neurologic function, in addition to the correction and preservation of vertebral alignment. The treatment of choice for patients with symptomatic spinal cord compression is surgical decompression,⁶ although specific tumors, such as neuroblastomas, may be appropriately treated with primary radiation or chemotherapy.¹⁸⁻²¹ Corticosteroids may be given in anticipation of definitive treatment, although no specific agent or regimen has demonstrated superiority.⁵

47.4.1 Biopsy

Biopsy may be an appropriate initial procedure; CT-guided or fluoroscopically guided and open procedures have been described. CT-guided biopsy may be technically difficult with small, firm tumors and those in contact with neural or vascular structures. Additional concerns include seeding of tumor cells along the biopsy tract, although the risk for this often-cited complication may in fact be overestimated.²² Techniques including transpedicular approaches with closure of the biopsy tract with methylmethacrylate or hydroxyapatite may reduce

the risk for tumor seeding.²³ Given the small amount of material obtained by needle or trocar, there is a possibility of nondiagnostic tissue or sampling error. Although needle biopsy of spinal lesions has become widely used, the potential for nondiagnostic tissue or misdiagnosis is relatively high (18%) in the case of benign primary bone tumors.²⁴

Open biopsy may be performed by a transpedicular approach, laminectomy, or costotransversectomy. Laminectomy may be appropriate for lesions in the epidural space. However, for lesions of the vertebral body without epidural extension, laminectomy may result in the spillage of tumor cells into the epidural space.²⁵ The incision used for biopsy should be planned such that it can be included within resection margins should en bloc or wide excision be required.

Biopsy may be unnecessary in cases of suspected metastasis from a known primary tumor, or those in which the imaging characteristics are highly suggestive of a specific tumor type for which an initial attempt at complete resection is appropriate, such as ABC or osteoid osteoma.^{4,7,15}

Oncologic Staging

Boriani et al²³ emphasized the importance of oncologic staging in spinal bone tumors to evaluate accurately the relationships of histology, management, and outcome. They applied and expanded the principles of the Enneking system (► Fig. 47.1) for classifying the stages of musculoskeletal tumors to the spine.^{23,25} The Enneking staging system divides benign tumors into three stages (S1, S2, and S3) and local malignant tumors into four stages (IA, IB, IIA, and IIB). Two additional stages include metastatic high-grade intra- and extracompartmental tumors (IIIA and IIIB).^{23,25} This grading system incorporates clinical characteristics, radiographic features on CT, MR imaging and isotope scanning, and histologic diagnosis.

The first stage of benign tumors is S1 (latent, inactive), during which tumors do not grow, or do so very slowly. These tumors have well-defined margins and are contained within a true capsule and do not extend beyond the anatomical compartment of

origin. Surgery is indicated in cases of neural compression or instability.^{26–28} S2 tumors are benign or active and grow slowly; they are bordered by a thin capsule and a layer of reactive tissue. The results of technetium Tc 99 per technetate bone scans are often positive, depending on the presence of osteoblastic activity, which is associated with deposition of tracer. These lesions may be treated with en bloc resection or intralesional excision, both of which have reported low recurrence rates.^{15,29–32} The recurrence rate is further lowered by the addition of cryotherapy, embolization, or radiation therapy in appropriate cases.²³ S3 tumors are aggressive, rapidly growing benign tumors with or without a thin or incomplete capsule and have the potential to invade adjacent structures, creating a wide, reactive, and highly vascular pseudocapsule. Appropriate treatment for S3 lesions is en bloc resection or intralesional excision followed by adjuvant therapy. Despite aggressive measures, recurrence is common.^{8,23,33,34}

Low-grade malignant tumors, stages IA and IB, have no true capsule, are surrounded by a wide reactive pseudocapsule, and should be treated by en bloc resection and adjuvant radiotherapy. Stages IA and IB are differentiated by containment of the tumor within the vertebral body (type IA) versus invasion of the paravertebral compartments (type IB). High-grade malignant tumors, stages IIA and IIB, grow rapidly; there is no pseudocapsule, leading to the formation of local tumor nodules, and the continuous seeding of neoplastic cells results in distant seeding. These tumors often result in pathologic fractures. The favored surgical approach includes wide en bloc resection, if possible, followed by radiation and chemotherapy according to tumor type.^{2,33,35–40} Stages IIIA and IIIB are differentiated from stage II tumors by the presence of distant metastases.

Surgical Staging

The first proposed staging system for spinal bone tumors was described by Weinstein and McLain⁸ and was subsequently revised by a team at the Rizzoli Institute in Bologna.^{23,25} The resulting classification, the Weinstein, Boriani, Biagini surgical

Enneking System – Site	
T0	Benign tumor confined within a true capsule and anatomic compartment
T1	Aggressive benign or malignant tumor confined within anatomic compartment
T2	Lesion has spread beyond anatomic compartment

Enneking System – Histological grade		Enneking System – Metastasis	
G0	Benign lesion	M0	No metastasis
G1	Low-grade malignant lesion	M1	Local or remote metastasis
G2	High-grade malignant lesion		

Enneking System – Stage			
Stage	Grade	Site	Metastasis
IA	G1	T1	M0
IB	G1	T2	M0
IIA	G2	T1	M0
IIB	G2	T2	M0
III	G1 or G2	T1 or T2	M1

Fig. 47.1 Enneking system for the classification of osseous tumors.²⁵

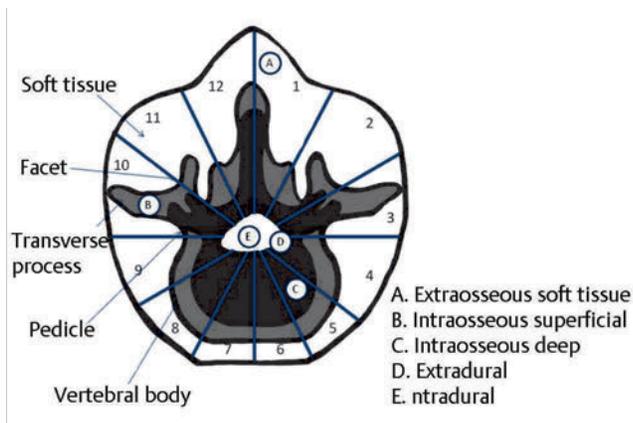

Fig. 47.2 The Weinstein, Boriani, Biagini surgical staging system. (After Boriani S, Weinstein JN, Biagini R. Primary bone tumors of the spine. Terminology and surgical staging. Spine [Phila Pa 1976] 1997;22 (9):1036–1044.²³)

staging system (► Fig. 47.2), uses location of the tumor within the vertebral column and bases the surgical approach on specific anatomical factors. Each vertebra is divided into 12 transverse radiating zones and 5 concentric layers, beginning in the paravertebral extrasosseous region and extending to the dura. Tumor location is further categorized within longitudinal zones based on the number of levels involved. The oncologic and surgical staging of each tumor affords a plan for resection and adjuvant therapy based on the specific characteristics of each case.

47.4.2 Indications for Surgical Treatment

Indications for surgical treatment include the preservation of neurologic function and the restoration or maintenance of mechanical stability.^{6–8} For many benign pathological processes (e.g., ABC or osteoid osteoma), resection may be curative.^{4,15,27,41,42} Malignancies involving the pediatric spine (e.g., neuroblastoma and rhabdomyosarcoma)^{10,19,43} usually require surgical intervention, most often as a key element of a multidisciplinary approach. Surgical management may include biopsy, tumor resection, and spinal stabilization.

47.4.3 Surgical Treatment

For cases in which it is deemed appropriate, en bloc resection remains the operative goal. Three basic approaches for en bloc excision, based on anatomical considerations, have been described: vertebrectomy, sagittal resection, and posterior arch resection.^{7,8,23,25}

Vertebrectomy is indicated if the tumor is confined to the vertebral body and at least one pedicle is spared (zones 4–8 or 5–9). Vertebrectomy begins with a posterior approach and excision of the posterior elements at the involved level, with stabilization, followed by an anterior approach for vertebrectomy and

anterior reconstruction. Depending on the involved spinal level, anterior resection may be performed by an anterior cervical approach, a transpleural thoracotomy, or a thoracoabdominal or retroperitoneal abdominal approach.²³

Sagittal resection is indicated when the tumor involves the vertebral body eccentrically, including the pedicle or transverse process (zones 3–8 or 8–10). Sagittal resection includes a posterior approach for excision of the posterior elements and pedicle, followed by an anterior approach for partial vertebrectomy and the completion of pedicle and transverse process removal.²³

Resection of the posterior arch alone is indicated when the tumor is located exclusively in the posterior elements (zones 10–3). Surgery includes a wide laminectomy and exposure of the dura above and below the involved levels, with extension laterally to the pedicles.²³

Instrumentation and stabilization, when required in children, should take into consideration the location and extent of initial tumor involvement, the spinal levels, and anterior/posterior element deficiency. Future growth capacity and the potential for asymmetric growth and progressive deformity are additional considerations in the pediatric population. Removal of more than two laminae and facetectomy both significantly increase the incidence of postoperative deformity.¹¹ As a general principle, the fewest number of levels possible should be included in the construct. Asymmetric fusion should be avoided, and the use of nonbiological interpositional materials (methylmethacrylate) and growth factors, such as recombinant bone morphogenetic protein (rBMP), should be cautiously considered.^{7,23}

47.4.4 Managing Spinal Deformity and Instability after Treatment

The risk for instability and progressive deformity after treatment of spinal column tumors is significant. Reported rates of instability after pediatric spinal tumor resection range from 24 to 100%.^{5,8,9,11,45,46} This may result from bone destruction by the tumor, resection of the tumor or extensive bone removal, neurologic impairment caused by the tumor or its treatment, or postoperative irradiation.⁴⁷ Although the extent of bone removal correlates with deformity, the extent or safety of tumor resection should not be compromised.

The surgical approach itself may result in immediate instability, particularly if multiple spinal levels are involved or if facetectomy is required. Patients with tumors involving more than one spinal column are at significant risk for immediate instability. In cases of immediate spinal instability, instrumentation at the time of initial surgery is indicated. Cases not requiring immediate postoperative stabilization may nonetheless develop instability and progressive deformity. The risk for delayed instability is higher in younger patients and in those undergoing multilevel laminectomy in the cervical or thoracic region.⁴⁷ Radiation therapy significantly elevates the risk for delayed deformity, with a reported incidence from 10 to 100%.⁴⁷ The degree of deformity has been shown to relate to the initial radiation dose and the duration of follow-up.⁴⁵

Numerous techniques have been suggested to mitigate the risk for postoperative deformity: limiting the number of

laminectomies performed, avoiding facetectomy, immediate rather than delayed spinal instrumentation, preservation of the intraspinal ligament, laminoplasty, posterior lateral fusion, and prophylactic orthotic treatment.^{11,47–49} Laminoplasty has been advocated as a technique for minimizing postlaminectomy kyphotic deformity; however, some authors suggest that the rate of deformity is not decreased.⁴⁶ Replacement of lamina (not infiltrated by tumor) after resection restores normal anatomy and may facilitate reoperation and/or subsequent fusion if required.

Surgical indications for treatment of postsurgical or postirradiation spinal deformity include the degree and rate of progression, pain, and neurologic impairment. Otsuka et al⁴⁷ advocate posterior instrumentation and fusion for cases of moderately severe but flexible kyphosis. Cases of severe and/or rigid kyphosis are treated with a combined anterior release or decompression and fusion augmented by posterior instrumentation and fusion. They reported no pseudoarthrosis and an average kyphosis regression of 5% during follow-up. They reported that bracing was ineffective in preventing the progression of kyphosis in all cases.⁴⁷

47.5 Primary Bone Tumors

47.5.1 Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and osteoblastoma are benign tumors and account for approximately 3% of all primary bone tumors.^{50,51} Osteoid osteoma accounts for 1.4% of primary spinal tumors and most commonly occurs in the second decade of life, with a male preponderance.²⁸ Ten percent of osteoid osteomas occur in the spine, with a large majority found in the posterior vertebral elements. Osteoblastoma is less common and has a peak incidence in the third decade of life.^{50,51} These tumors have a similar

histology, with bone formation by osteoblasts producing osteoid and woven bone. They are differentiated primarily by size, intraoperative appearance, and behavior. Osteoblastomas are larger than 1 to 1.5 cm and more vascular, and they are more likely to involve the vertebral body.⁵² Although exceedingly rare, cases of malignant transformation have been reported.⁵³ Osteoid osteomas typically have a sclerotic pattern, appearing hyperdense and expansile, without bone destruction. On MR imaging, high signal intensity on T2-weighted images of the surrounding muscle and bone is seen. Radiographically, osteoblastomas more commonly have a ground glass appearance on CT. They usually occur in cancellous bone of the lamina or pedicles of the cervical or lumbar spine.

Osteoid osteoma (► Fig. 47.3) commonly presents with localized pain, although radicular pain may be present because of nerve root irritation.⁵⁰ Other clinical findings may include point tenderness, scoliosis,⁹ and neurologic deficit.⁵¹ The pain is often severe and intermittent and is worsened by activity. Often, nocturnal pain relieved by nonsteroidal anti-inflammatory medications or aspirin is noted.⁵⁰ Osteoblastoma (► Fig. 47.4), shares many of the clinical features of osteoid osteoma; however, neurologic deficit is more common because of the larger size of this lesion.²⁸ The onset of symptoms may precede detectable abnormality on plain radiographs or CT. MR imaging and radioisotope bone scans may detect lesions not initially identified on plain radiographs or CT.^{54,55}

Observation alone may be appropriate management for small, intermittently or minimally symptomatic lesions consistent with osteoid osteoma. Spontaneous remission and involution may occur. In patients with persistent pain or neurologic deficit, gross total excision is the surgical goal. Osteoid osteoma appears firm and sclerotic with an occasional fibrotic or granulomatous component, whereas osteoblastoma more typically a friable, hemorrhagic mass, well circumscribed from the normal surrounding bone.

Fig. 47.3 This 5-year-old boy presented with severe dysesthetic pain of the right upper extremity. On examination, he had torticollis and weakness of the right deltoid and bicep. (a) Axial computed tomography shows a sclerotic lesion of the lateral mass and pedicle with a typical “ground glass” appearance, consistent with osteoid osteoma. (b) On sagittal T1-weighted magnetic resonance imaging, the lesion is hypointense. (c) The lesion was resected, and segmental posterior fusion with lateral mass screws was completed.

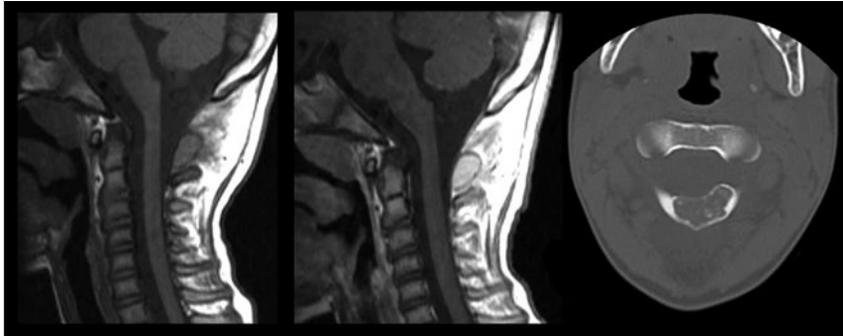

Fig. 47.4 This 17-year-old boy presented with persistent neck pain and torticollis. Osteoblastoma. (Courtesy of Dr. David Harter and Dr. Sarah Milla.)

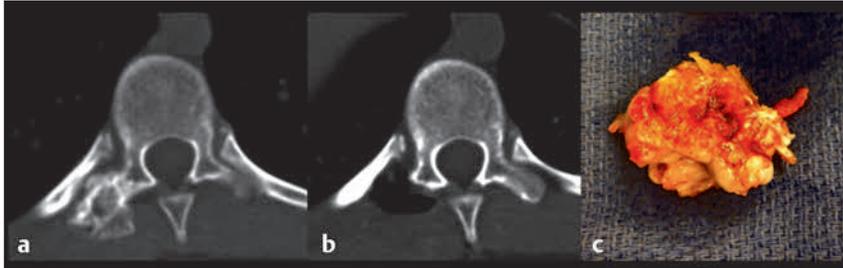

Fig. 47.5 This 15-year-old boy presented with back pain. (a) Axial noncontrast computed tomography demonstrates a lesion originating from the T10 transverse process. (b) The lesion was removed en bloc. (c) Osteochondroma.

Results of surgery are usually excellent for symptomatic relief and tumor control. However, the risk for local recurrence remains, with most series reporting a recurrence rate of approximately 10%.^{27,28,51} Intraoperative localization may be challenging, given the small size and sclerotic appearance of these lesions. Techniques, including preoperative CT-guided dye injection or guidewire placement and intraoperative radioisotope bone scanning, have been described.^{56,57} Although the estimated risk for radiation-induced malignancy is low (<1%),⁵⁸ reoperation rather than radiotherapy is recommended for recurrent or residual osteoid osteomas.^{27,50,51,53,55} CT-guided radiofrequency ablation and other techniques have also been described for the “deactivation” of osteoid osteoma with good results.^{59,60}

47.5.2 Osteochondroma and Osteosarcoma

Osteochondromas (► Fig. 47.5) account for 30 to 40% of benign osseous tumors and 4% of solitary spine tumors. They may occur as solitary, sporadic lesions or multifocally in the setting of an autosomal-dominant syndrome—hereditary osteochondromatosis. Approximately 1 to 7% of all osteochondromas occur in the spine. Solitary spinal lesions on average occur toward the end of the third decade of life, whereas multiple lesions occur earlier, toward the beginning of the third decade of life.²⁶ There is a significant male preponderance (2.5:1).^{26,61} Osteochondromas commonly affect the cervical spine, with approximately 50% of cases reported there.^{26,61,62} Osteochondromas can involve multiple contiguous vertebral levels and encroach upon the spinal canal and neural foramina, resulting in spinal deformity and neurologic impairment.^{26,61}

Given the cartilaginous quality of these tumors, plain radiographs are often normal. CT and MR imaging are often required

for the diagnosis. As for other benign spinal tumors, complete excision is usually curative, with excellent reported neurologic and functional outcomes.

Malignant transformation occurs in approximately 10% of cases, resulting in osteosarcoma. Although they are very uncommon in children, a small number of spinal osteosarcomas have been reported.^{63,64} The prognosis for spinal osteosarcoma remains poor, even with contemporary, multimodal treatment at experienced centers.^{65,66} The presence of metastatic disease and the inability to achieve en bloc resection are significant negative prognostic factors.^{65,66}

47.5.3 Aneurysmal Bone Cyst

ABCs occur most commonly in children and adolescents (median age, 10.2 years).⁶⁷ These expansile, vascular lesions have no known cause, although they have been reported to occur in conjunction with other pathologic conditions, such as giant cell tumor, fibrous dysplasia, and osteoblastoma.^{41,42,68} Histologically, the lesions often have a hemorrhagic component, with hemosiderin-containing macrophages; other features are multinucleated giant cells, fibrous tissue, and expansion of the cortical margins. Localized pain, worse with activity, is common. Neurologic symptoms occur as the lesion encroaches upon the neural foramina or spinal canal. Pathologic fracture or spinal instability may occur as the normal vertebral elements are replaced.

Radiographically, these lesions appear distinct—expansile, eccentrically located masses with fluid–fluid levels in the central region of trabeculae surrounded by a thin “eggshell” rim of cortical bone. They are often primarily located in the posterior elements, although they may also extend into the pedicle and vertebral body (► Fig. 47.6). There may be a significant soft tissue component, with variable enhancement on MR imaging or CT. Radionuclide bone scan may show areas of

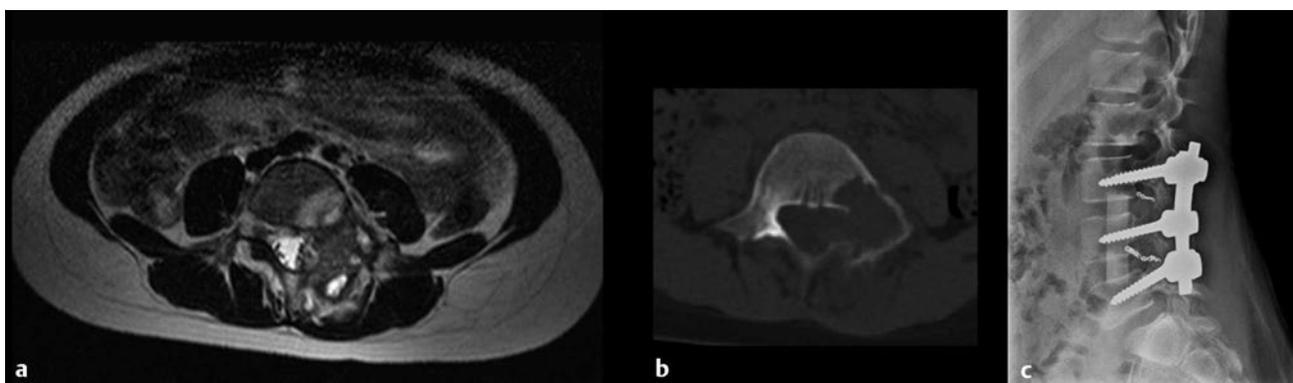

Fig. 47.6 This 8-year-old girl presented with persistent back pain that extended down the left lower extremity. She had paraspinal tenderness and weakness of the left dorsiflexors. (a) T2-weighted magnetic resonance imaging demonstrates a complex mass involving the lamina, pedicle, and vertebral body of L4, consistent with aneurysmal bone cyst. (b) Computed tomographic scan shows a thin rim of cortical bone. Preoperative angiography and embolization were performed. (c) The lesion was removed by a posterior approach, and primary reconstruction was performed with allograft and posterolateral fusion (note coils from embolization). (Courtesy of Dr. Joseph Dryer, New York University.)

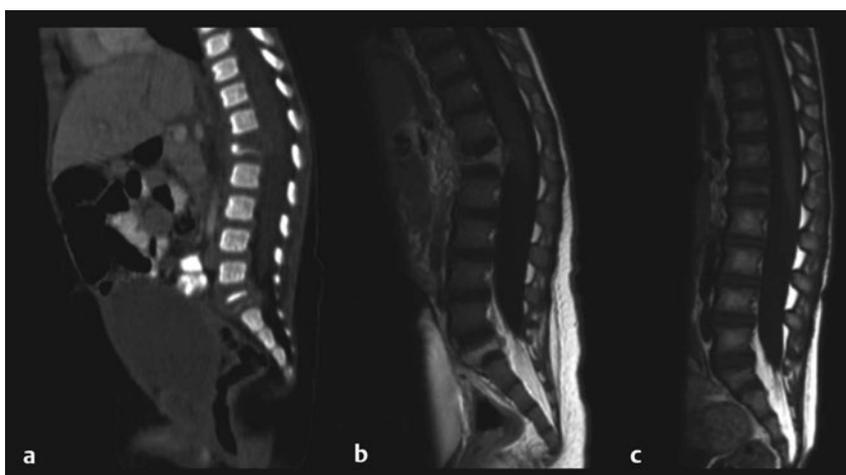

Fig. 47.7 At the age of 9 months, this infant boy presented with weight loss and a palpable skull mass. Biopsy confirmed Langerhans cell histiocytosis. (a) Computed tomographic scan with sagittal reconstruction. Lytic lesions of L1 and S1 are seen. Note the kyphotic deformity. (b) Magnetic resonance (MR) image with gadolinium. Vertebra plana with an associated enhancing epidural component. (c) Follow-up sagittal MR image after chemotherapy and bracing. There has been partial reconstitution of the vertebral bodies, and the degree of kyphosis has diminished.

peripheral uptake and a central area of hypoactivity within the cystic component. Arteriography often shows a highly vascular lesion with extensive collateral formation. Preoperative embolization, on a case-by-case basis, is advocated by many centers because blood loss may be significant.^{15,30,31} Embolization should be considered for large ABCs, those that involve multiple vertebral levels, and those with significant ventral extension. Intraoperative fatality from uncontrolled hemorrhage has been described.³¹ Although biopsy has been performed safely,^{24,69} the unique radiographic appearance of these lesions often obviates the need for histologic diagnosis before definitive surgical treatment.

ABCs are often locally aggressive, and gross total excision remains the goal. En bloc resection is usually not feasible; intralesional curettage is more commonly performed.^{14,15,30,31,41} Complete resection should be pursued because residual ABCs have a high propensity for progressive enlargement, with a recurrence of symptoms. Residual or recurrent ABC found after an initial attempt at resection is not uncommon, with reported rates of 10 to 14%.^{15,30,31} Although delayed recurrence is possi-

ble, recurrence within 6 months is more common.³¹ Resection of recurrent or residual ABC is the treatment of choice. These lesions may involve multiple vertebral segments or anterior and posterior columns, necessitating stabilization at the time of excision.^{14,15,30,31,41} Long-term follow-up is advisable because ABC may occur in conjunction with another condition, such as giant cell tumor or osteoblastoma, that may require additional treatment.^{41,42,68}

47.5.4 Eosinophilic Granuloma

Eosinophilic granulomas (► Fig. 47.7) are benign, destructive lesions characterized by the presence of abnormal histiocytes, known as Langerhans cells. They may be solitary or involve multiple organ systems, as in the following syndromes: histiocytosis X, Hand-Schüller-Christian disease, and Letterer-Siwe disease.⁵¹ Solitary eosinophilic granulomas occur most commonly in the skull, femur, mandible, ribs, pelvis, and spine. The cervical and thoracic segments are most commonly involved. Eosinophilic granuloma of the spine usually affects

Fig. 47.8 This 16-year-old boy presented with back pain and leg pain. (a) Sagittal magnetic resonance image with gadolinium identifies a large sacral mass. Angiography (b) before and (c) after embolization. Giant cell tumor. Resection was performed by a posterior approach.

the anterior column, with infiltration and erosion of the vertebral body and preservation of the adjacent intervertebral disks. The presentation is usually in childhood or adolescence with localized pain, which may be gradual or acute in onset; a history of minor trauma is not unusual. Neurologic deficit can also occur as a result of nerve root irritation or compression or spinal cord compression. Spinal deformity may also occur.

The radiographic findings of eosinophilic granuloma include a lytic, nonsclerotic, sharply defined lesion. Involvement of the adjacent vertebral segments and ribs may be identified. Vertebral body collapse may result in the characteristic vertebra plana. Plain radiographs and CT scans often show bony destruction and deformity. MR imaging may show enhancement of the soft tissue around the involved bone and also document involvement of the spinal canal or neural foramen. Because these lesions may be metabolically inactive, radioisotope bone scans may demonstrate no uptake within the lesion. Open or CT-guided biopsy is used to obtain tissue for definitive diagnosis.

The treatment of spinal eosinophilic granuloma is individualized based on the clinical presentation. For patients with acute neurologic deficit or significant spinal deformity, primary surgery may be indicated for diagnosis and the preservation or restoration of neurologic function and spinal stability.^{70,71} For patients without significant neurologic compromise or spinal deformity, observation or bracing alone may be warranted.⁷⁰ Radiotherapy has been shown to be effective, as has CT-guided intralesional corticosteroid injection.⁷²

47.5.5 Giant Cell Tumor

Most spinal giant cell tumors occur in the sacrum (► Fig. 47.8). They are more common in women. Spinal giant cell tumors are usually expansile and radiolucent. They may enlarge and involve the sacroiliac joints. Giant cell tumor outside the sacrum often involves the vertebral body. Imaging findings may be similar to those of ABC on CT, angiography, and nuclear bone scan. Like ABC, giant cell tumor is often locally aggressive, with high reported recurrence rates. En bloc resection is usually not feasible, and most are treated with internal curettage.^{29,41} Selective embolization may facilitate surgery and has also been used as treatment alone.¹⁷ Recently, successful medical therapy with bisphosphonates has been reported.^{73,74} Given the benign histologic nature of giant cell

tumor, radiation therapy is reserved for surgically inaccessible lesions.⁷⁵

47.6 Malignant Tumors

47.6.1 Neuroblastoma

As the most common extracranial solid tumor in children, and the most common neoplasm in infants, neuroblastoma is likely the most common malignant spine tumor treated by pediatric neurosurgeons. Arising from the sympathetic nervous system, adrenal glands, and ganglia of the thoracic, cervical, and pelvic regions, neuroblastomas may grow to massive size before the development of spinal involvement. Typically, epidural extension of the tumor occurs through one or more neural foramina, resulting in a dumbbell configuration. Ganglioneuroma and rhabdomyosarcoma may have a similar radiographic appearance.⁵ Metastatic spinal lesions may also occur, although usually as a late manifestation of disseminated disease. The thoracic and lumbar levels are most commonly affected. Interestingly, the survival of patients with symptomatic spinal cord compression is higher than that of patients without this finding.⁷⁶ Overall 5-year survival rates are 71%.¹⁹

Neuroblastoma with spinal involvement often appears as a dumbbell-shaped mass with a large paravertebral component (► Fig. 47.9). Compression and displacement of the spinal cord by epidural tumor are more common than mass effect due to osseous metastasis. Plain radiographs may demonstrate erosion of the pedicle, scalloping of the vertebral body, or widening of the spinal canal. These tumors usually appear homogeneous on noncontrast imaging and heterogeneous on postcontrast studies.

The indications for surgical decompression of epidural neuroblastoma are balanced against the degree and duration of neurologic deficit, the risk for postoperative deformity, and the chemo- and radiosensitivity of this tumor.¹⁹ High-risk patients with spinal involvement and minimal or no neurologic deficit should be offered chemotherapy. Patients with significant deficit due to cord compression may respond to chemotherapy, with the understanding that some may require operation for progressive neurologic deficit. Chemotherapy may be avoided in low-risk patients who are potentially curable with operation alone.⁷⁶⁻⁷⁸ Patients treated with surgery or chemotherapy for epidural disease often have residual neurologic dysfunction or spinal deformity. Punt et al reviewed 122 patients with spinal

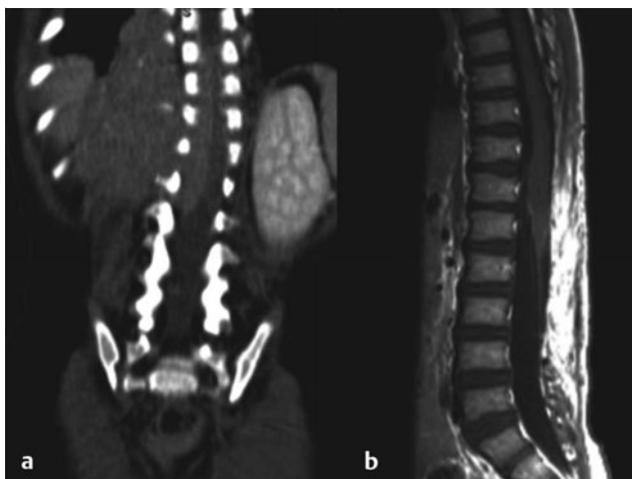

Fig. 47.9 This 11-month-old boy presented with irritability and progressive paraparesis. (a) Computed tomographic scan with coronal reconstruction demonstrates a large thoracic paravertebral mass extending through multiple neural foramina, with spinal cord compression. Multilevel laminectomy rather than laminoplasty was performed because of bone infiltration. Neuroblastoma. (b) Sagittal postcontrast magnetic resonance image shows moderate kyphotic deformity, no evidence of tumor.

cord compression due to neuroblastoma. After a median 8-year follow-up, most (71 of 99) had problems: motor impairment (43%), scoliosis (31%), impaired bladder function (26%), constipation (19%), impaired cutaneous sensibility (17%), growth delay (14%), and neuropathic pain (5%). The initial treatment had no clear impact on the frequency of late effects.⁷⁸ The Pediatric Oncology Group reviewed 83 patients treated with laminectomy or laminectomy with chemotherapy and/or radiotherapy versus chemotherapy or radiation alone. They reported scoliosis rates of 29% and 2% for patients with and without laminectomy, respectively. They advised laminectomy only for patients with progressive neurologic symptoms after the initiation of chemotherapy.¹⁹

47.6.2 Rhabdomyosarcoma

Rhabdomyosarcoma accounts for 8% of pediatric solid tumors. Spinal involvement may present in a manner similar to that of neuroblastoma, a dumbbell-shaped tumor with a large paraspinous component (► Fig. 47.10). Rhabdomyosarcoma, like neuroblastoma, is sensitive to chemotherapy and radiation therapy; the rationale for surgical intervention is similar.⁷⁹

47.6.3 Ewing Sarcoma

Ewing sarcoma is the most common nonlymphoproliferative primary malignant spinal tumor in children. There is a spinal origin in 3 to 10% of cases, and metastatic lesions of the spine may also occur. Ewing sarcoma typically presents between the ages of 10 and 20 years; the sacrococcygeal region is most commonly involved, followed by the lumbar and thoracic levels. Lesions are typically centered in the vertebral body but can extend into the posterior elements. Plain radiographs demonstrate areas of bone lysis, expansion, or sclerosis (► Fig. 47.11).

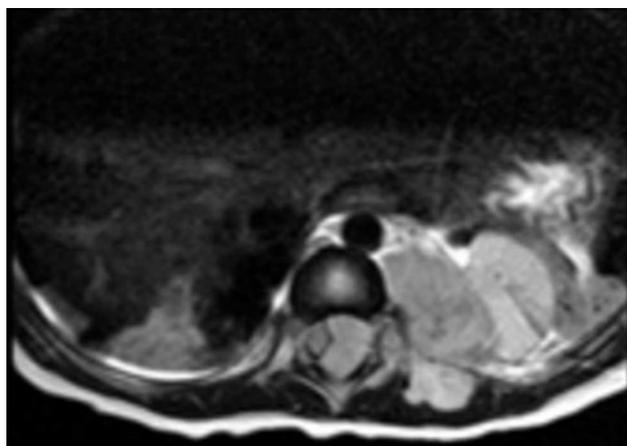

Fig. 47.10 This 2-year-old girl presented with progressive paraparesis and a large paravertebral component with displacement and compression of the spinal cord. Rhabdomyosarcoma. She underwent laminoplasty laminectomy and subsequent thoracotomy for tumor resection followed by chemotherapy.

CT and MR imaging demonstrate a surrounding soft tissue mass and reactive change; however, no specific radiographic criteria are established. Histologically, these lesions are highly mitotic, poorly differentiated and pleomorphic. Intraoperatively, they appear firm, gray, and friable, with hemorrhage and necrosis.

The treatment of Ewing sarcoma has evolved, and outcomes have improved considerably.^{35,36,80} Current treatment recommendations include biopsy with initial chemotherapy and radiation for high-grade malignancies, with second-look surgery for residual tumor when appropriate. Resection for histologically low-grade tumors, followed by adjuvant chemotherapy and radiation, is suggested.^{5,37,81}

Location remains an important prognostic factor. Sacral lesions often reach a large size before diagnosis, making en bloc resection difficult.³³ Lesions of the mobile spine often present earlier, facilitating diagnosis and treatment. Attempts at resection should avoid piecemeal or intralesional approaches and should favor en bloc resection with negative tumor margins.^{33,35} Other favorable factors include younger age (younger than 10 years), tumor volume of less than 100 mL, a positive response to chemotherapy (>90% volume reduction), and en bloc resection.³⁵ Negative prognostic factors include metastatic disease, tumor larger than 8 cm, elevated white blood cell count and erythrocyte sedimentation rate, and less than 90% reduction of tumor volume with chemotherapy.⁴⁰ Current estimates for 5-year survival after multimodality treatment range from 33 to 74%.^{33,36}

47.6.4 Chordoma

Chordoma is a locally aggressive tumor derived from the malignant transformation of notochordal remnants. Chordoma is a rare tumor during childhood, accounting for 5% of all malignant primary bone tumors. Chordomas in children are most commonly located in the midline of the skull base at the sphenocipital junction, followed by the mobile spine, and finally the sacrococcygeal region.⁸² They are slow-growing tumors, and symptom progression (pain, numbness, and weakness) is often

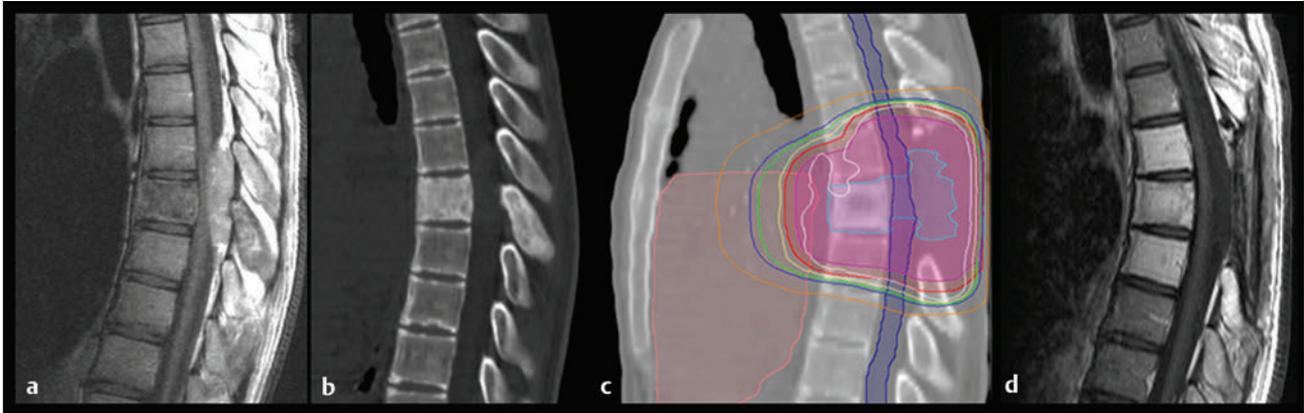

Fig. 47.11 This 16-year-old boy presented with a progressive paraparesis, back pain, and a midthoracic sensory level. He underwent emergent laminectomy for resection of an epidural tumor followed by adjuvant chemotherapy and radiotherapy. Ewing sarcoma. (a) Contrast-enhanced sagittal magnetic resonance (MR) image. (b) Sagittal reconstruction of a computed tomographic (CT) scan. (c) Immediate postoperative CT scan with radiation dosimetry. (d) Follow-up contrast-enhanced sagittal MR image 5 years after surgery. No active tumor is seen. Laminectomy defect and moderate thoracic kyphosis. (Courtesy of Dr. David Harter, Dr. Elizabeth Raetz, and Dr. Ashwatha Narayana.)

Tumortype	Age	Location	Histology	CTfindings	MRIfindings	Treatment
Osteoma	1 st -2 nd decade	Cervical and lumbar, posterior elements	Hypodense tumor surrounding normal trabeculae	Low density center with surrounding sclerosis, <1-1.5 cm	Nidus-T1 isointense, T2 hypointense, Nidus enhancement	Resection or ablation
Osteoblastoma	3 rd decade	Cervical and lumbar, posterior elements	Distinct margin, osteoblasts, osteoclastic giant cells	Low density center with surrounding sclerosis, >1 cm	Reactive marrow, soft tissue edema	Resection
Osteochondroma	2 nd decade	Thoracic and lumbar, posterior elements	Cartilage formation	Ring/arc calcifications	Cartilage cap, T1 hypointense – T2 hyperintense,	Resection
Osteosarcoma	3 rd -6 th decade	Lumbar and sacral, posterior elements	Spindle cells, immature bone	Variable, lytic or sclerotic	T1 hypointense, T2 hyperintense	Multimodal, excision, XRT and chemotherapy
Aneurysmal bone cyst	2 nd decade	Equal, posterior elements, pedicle and vertebral body	Cavernous cyst with walls of woven bone	Expansile, eggshell cortex	Fluid levels, hemorrhage, soft tissue edema	Resection +/- preoperative embolization
Eosinophilic granuloma	1 st -2 nd decade M>F	Cervical, thoracic, vertebral body	Langerhans' cells	Lytic destruction, vertebra plana	Preserved disc spaces, enhancing epidural mass	Observation, biopsy, excision

Fig. 47.12 Common characteristics of pediatric epidural spinal tumors.

insidious. Dissemination, although rare, has been reported within and outside the neuraxis.⁸³

Given that the notochord is the embryologic source of the nucleus pulposus, initial involvement of the vertebral body is expected. Radiographically, osteolysis with a large associated soft-tissue mass is typical. Histologically, chordomas are usually contained within a pseudocapsule and are characterized by the presence of physaliphorous cells containing intracytoplasmic vacuoles and abundant mucin.^{82–84}

Current surgical recommendations include en bloc resection with tumor-free margins. Proton beam radiotherapy is recommended for residual tumor or recurrence.⁸⁵ Reported 5-year survival rates approximate 50%.^{84,86}

47.6.5 Epidural Metastasis

Children with solid malignant tumors may develop an epidural spinal metastasis or osseous metastasis with extension into the epidural space, causing spinal cord compression. Studies report that from 3 to 5% of all children with malignant solid tumors develop epidural spinal metastases.^{87,88} Among children with spinal cord compression, 17.9% had Ewing sarcoma, 7.9% neuroblastoma, 6.5% osteosarcoma, and 4.9% rhabdomyosarcoma. Other diagnostic considerations include lymphoproliferative disorders, sarcomas, germ cell tumors, and others. Spinal cord compression (weakness, pain, or myelopathy) occurs as the presenting symptom in approximately 10% of pediatric patients with epidural metastases.⁸⁷ The treatment and prognosis depend upon the primary tumor; of particular importance is sensitivity to adjuvant therapy, including chemotherapy and radiation therapy.⁸⁸

47.7 Conclusion

Pediatric spinal tumors often present with pain. The diagnosis is often suggested by the clinical history. Physical examination may show signs of spinal deformity or neurologic deficit. Imaging with plain radiographs often shows scoliosis or osteolytic or osteoblastic lesions. MR imaging and CT allow excellent visualization of the neural and osseous structures. Biopsy may be useful to guide definitive therapy, although it is not uniformly required. Surgery for benign lesions should be undertaken with curative intent. For locally aggressive benign tumors and contained malignancies, an attempt at en bloc resection followed by adjuvant therapy is suitable. Spinal deformity may be a presenting symptom or may result from treatment and should be treated if progressive or symptomatic. Multidisciplinary approaches have improved the functional and oncologic outcomes for many of these disorders.

47.8 Acknowledgments

We thank Dr. Joseph Dryer, Dr. Ashwatha Narayana, Dr. Elizabeth Raetz, and Dr. Sarah Milla for contributing clinical examples. We also thank Emily E. Harter for production of the figures.

Pearls

- Radionuclide bone scan should be considered for children with persistent symptoms and negative findings on radiography, CT, and MR imaging.
- Preoperative embolization should be considered for ABCs and giant cell tumors.
- The surgical goal for benign spinal tumors is cure.
- Locally aggressive tumors and primary malignancies are ideally treated with en bloc resection and adjuvant therapy.
- Spinal instability is common among children with spinal tumors and should be treated when it is progressive or symptomatic.
- Children have a significant chance of meaningful recovery, even when they present with severe neurologic impairment due to neoplastic spinal cord compression.

48 Neurofibromatosis 1 and 2

Ian F. Pollack

Neurofibromatosis is a descriptive term that was coined by Frederick von Recklinghausen in 1882 to characterize the cutaneous tumors of two patients that were thought to be composed of a combination of neural and mixed cellular elements. This diagnostic category was later expanded to incorporate an array of dermatologic, ocular, and nervous system manifestations; thus, it was included with the broader group of disorders referred to as phakomatoses. In the ensuing decades, investigators realized that patients with NF could be categorized into distinct clinical groups based on the pattern of neural and extraneural manifestations.¹ Improvements in imaging techniques and advances in molecular genetics have facilitated these efforts and allowed clinicians to confidently classify patients as having neurofibromatosis 1 (NF-1, previously known as *peripheral neurofibromatosis*) or neurofibromatosis 2 (NF-2, previously known as *central neurofibromatosis*), and they have also identified phenotypically similar variants that are distinct entities.^{2,3}

The importance of recognizing these disorders stems from the fact that the natural history of a neoplasm, such as a peripheral nerve tumor or an optic glioma, may be significantly different depending on whether or not the lesion arises in a person with NF. In addition, the indications for therapeutic intervention, the hierarchy of treatment options, and the long-term management goals may differ substantially for patients with NF-related versus sporadic tumors. Finally, recognition of the diagnosis is an essential step in providing appropriate multidisciplinary evaluation and counseling to affected patients and their families. This chapter focuses on the diagnostic and therapeutic issues that arise in children with NF-1 and NF-2; other phakomatoses are discussed in the following chapter.

48.1 Epidemiology, General Diagnostic Criteria, and Molecular Pathogenesis

NF-1 is one of the most common genetic disorders, affecting 1 in 3,000 to 1 in 4,000 people.^{4,5} The mode of inheritance is autosomal-dominant, and approximately 50% of cases arise sporadically as new mutations. The syndrome results from mutations or deletions of a gene on chromosome 17q11.2 that encodes a large protein called neurofibromin. A portion of this protein is a guanosine triphosphatase (GTPase) activator^{6,7} that plays a role in signal transduction by favoring conversion of the active GTP-bound form of Ras and related G-proteins to the inactive guanosine diphosphate (GDP)-bound form.⁸ The NF-1 gene functions as a classic tumor suppressor gene in that loss of both alleles is needed for tumorigenesis. Because patients with NF-1 are born with only one normal copy of the gene, a single mutation or deletion that inactivates the second allele is theoretically sufficient to favor tumor formation,⁹ although additional molecular events may also contribute.¹⁰

Affected patients exhibit a combination of café au lait macules, Lisch nodules (iris hamartomas), axillary and inguinal

freckling, skeletal lesions such as sphenoid wing dysplasia and thinning of long bone cortices, and optic gliomas, as well as an increased incidence of other central nervous system and systemic tumors.^{10–15} Diagnostic criteria that reflect the diverse manifestations of NF-1 were proposed at a National Institutes of Health (NIH) Consensus Development Conference¹⁶ (see box “NIH Consensus Criteria for the Diagnosis of Neurofibromatosis 1”¹⁶). They were devised, in part, for high specificity (i.e., to have a low rate of false-positive diagnoses). Because many of the characteristic stigmata, such as Lisch nodules, are not usually apparent in infancy, ongoing follow-up is sometimes required to establish the diagnosis conclusively. In a large study of patients with sporadic NF-1, 54% of children met diagnostic criteria by 1 year of age, 97% by 8 years, and 100% by 20 years.¹⁷ The exclusion of non-NF-1 variants, such as Proteus syndrome (the original “elephant man” disease that was mistaken for NF-1) and Legius syndrome, has been facilitated by genetic testing when clinically warranted.²

NIH Consensus Criteria for the Diagnosis of Neurofibromatosis 1

The diagnostic criteria are met if a patient has two or more of the following:

- Six or more café au lait macules that have a maximum diameter of more than 5 mm in prepubertal patients and more than 15 mm in postpubertal patients
- Two or more neurofibromas of any type, or one or more plexiform neurofibromas
- Freckling in the axillary or inguinal region
- Optic glioma
- Two or more Lisch nodules (iris hamartomas)
- A characteristic osseous lesion, such as sphenoid wing dysplasia or thinning of the long bone cortices, with or without pseudarthrosis
- A first-degree relative (i.e., parent, sibling, or child) with NF-1 by the above criteria

Source: National Institutes of Health Consensus Development Conference. Neurofibromatosis. Conference statement. Arch Neurol 1988;45(5):575–578.¹⁶

NF-2 is less common than NF-1, affecting 1 in 25,000 to 1 in 50,000 people.^{18,19} This disorder reflects mutations or deletions involving a gene at chromosome region 22q12 that encodes a protein referred to as merlin (*moesin-, ezrin-, and radixin-like protein*); merlin is involved in linking cytoskeletal elements with plasma membrane proteins.²⁰ Affected patients have a combination of eighth nerve and other cranial nerve neurilemmomas, meningiomas, glial neoplasms, neurofibromas, and juvenile posterior subcapsular cataracts (see box “Consensus Criteria for the Diagnosis of Neurofibromatosis 2”¹⁶). As in patients with NF-1, the diagnosis in patients without a positive family history may be difficult initially because many children will not manifest sufficient findings to satisfy diagnostic criteria

conclusively, and they may present at a young age with isolated nervous system tumors, such as spinal cord ependymomas and unilateral vestibular schwannomas.^{21,22} In such “suspected” cases, ongoing surveillance is warranted.

Consensus Criteria for the Diagnosis of Neurofibromatosis 2

The diagnostic criteria are met if a person has either of the following:

- Bilateral eighth nerve masses seen with appropriate imaging techniques, such as magnetic resonance imaging or computed tomography
- A first-degree relative with neurofibromatosis 2 and a unilateral eighth nerve mass or two of the following:
 - Neurofibroma
 - Meningioma
 - Glioma
 - Neurilemoma
 - Juvenile posterior subcapsular cataract

Source: National Institutes of Health Consensus Development Conference. Neurofibromatosis. Conference statement. Arch Neurol 1988;45(5):575–578.¹⁶

A distinct subgroup of patients with features of NF-1 and NF-2 exhibit signs restricted to certain segments of the body. In the most typical situation, patients will have café au lait macules and neurofibromas on one extremity or one-half of the body and may have Lisch nodules in the ipsilateral eye. This so-called segmental form of NF-1 accounts for 5% of patients with NF-1 and arises from mosaicism, in which mutations of the *NF1* gene occur at some time after fertilization in the developing embryo.^{3,13,23} If gonadal progenitors are spared (i.e., there is just somatic mosaicism), then this form of the disorder is not genetically transmissible. If both gonadal and somatic cells are involved, then a potential exists for genetic transmission, which varies from nearly zero (if a small percentage of gonadal cells are involved) to 50% (if all gonadal cells are involved). A segmental form of NF-2 has also been suggested for patients who have multiple discrete neurilemmas involving peripheral nerves of an extremity without central features of NF-2.²³

Even among patients with typical (nonsegmental) NF-1 or NF-2, there is significant variability in the severity of manifestations between members of different families. The basis for this symptomatic heterogeneity may in part reflect differences in the specific site of mutations in the *NF1* or *NF2* genes themselves²⁴: patients with large deletions involving the *NF1* locus and surrounding genes tend to have a more severe phenotype than those with point mutations,²⁵ whereas those with small in-frame gene deletions have a milder variant.²⁶ The results of increasingly available genetic tests, such as protein truncation assays, fluorescent in situ hybridization, and direct sequencing, correlated with the clinical features, should shed further light on this issue during the next few years and should also help to resolve the diagnostic uncertainty that often surrounds patients who meet only one criterion for NF-1 or NF-2. However, an important caveat in interpreting these genetic

studies is that the exact features of NF-1 and NF-2 can vary widely within a single family (in which all affected individuals should have an identical *NF* mutation), reflecting the likely involvement of other disease-modifying genes or interacting environmental factors. Thus, contemporary genetic testing can predict the occurrence of NF-1 or NF-2, but not its severity in most cases.²⁴

48.2 Diagnostic Evaluation

Box “Suggested Screening Studies for Children with Proven or Presumptive Neurofibromatosis 1” and box “Suggested Screening Studies for Children with Proven or Presumptive Neurofibromatosis 2” summarize the baseline evaluations that are recommended in children with proven or suspected NF-1 or NF-2. Similar suggestions for health supervision in children with NF-1 have been published by the Committee on Genetics of the American Academy of Pediatrics.²⁷ Such recommendations represent guidelines rather than requirements, and as such, they are followed with flexibility and judgment. They incorporate a detailed screening of the major systems involved by each of the disorders, particularly the skin, eyes, nervous system, and spine, and provide a basis for a more detailed evaluation of other systems if concerning findings are detected on a screening evaluation. For example, children with NF-1 or NF-2 do not undergo routine imaging of the chest and abdomen, but such studies are employed for those who present with symptoms of dyspnea, abdominal discomfort, or distention, which may be referable to an enlarging thoracoabdominal tumor. Similarly, a comprehensive endocrine evaluation coupled with cranial magnetic resonance (MR) imaging is pursued in children with NF-1 who manifest precocious puberty, growth delay, or other evidence of endocrinopathy that may be related to hypothalamic involvement by tumor. Finally, because children with NF-1 often exhibit varying degrees of cognitive impairment that may interfere with their school performance and socialization,^{28,29} detailed neuropsychological testing is often pursued, but the need for this testing is determined on a case-by-case basis.

Suggested Screening Studies for Children with Proven or Presumptive Neurofibromatosis 1

- Annual clinical examination including neurologic assessment and dermatologic evaluation
- Annual ophthalmologic examination
- Magnetic resonance (MR) imaging examination of the head
 - Children diagnosed before 5 years of age
 - Children with new neurologic deficits, visual loss, or endocrinopathy
- MR examination of the spine and plain radiographs
 - Children with scoliosis
 - Children with back pain, radiculopathy, or long tract signs referable to the spine
- Neuropsychological and developmental testing
 - Children with learning, speech, or socialization difficulties or impaired fine motor skills
- Genetic counseling should be offered to the family at diagnosis and as needed on an ongoing basis.

Suggested Screening Studies for Children with Proven or Presumptive Neurofibromatosis 2^a

- Neurologic examination
- Ophthalmologic examination
- Audiogram
- Magnetic resonance imaging of the head and spine
- Genetic counseling should be offered to the family at diagnosis and as needed on an ongoing basis.

^aThe frequency with which these tests are repeated depends on whether abnormalities are identified on the initial evaluation. At the least, all tests should be repeated approximately every 3 to 5 years. Annual examinations are recommended for children with known lesions.

An important element in the evaluation of such children is the need for a comprehensive approach to patient care, often best provided in the setting of a multidisciplinary clinic. This approach facilitates efforts to diagnose and treat the child as an individual rather than as a collection of affected organ systems and ensures that management and counseling proceed in a coordinated fashion. A discussion of the major nonneurologic and neurologic manifestations of these disorders and their diagnosis and management is provided below.

48.2.1 Nonneurologic Manifestations

Because both NF-1 and NF-2 are multisystem disorders, patients often present with symptoms and signs not directly referable to a nervous system tumor. Appropriate recognition of the significance of these findings and knowledge of the indications for diagnostic and therapeutic intervention are essential for optimizing functional outcome.

Neurofibromatosis 1

Café au lait macules and axillary freckling are often a source of concern but are of no serious clinical significance. These lesions result from abnormal collections of melanin pigment in affected melanocytes, which harbor loss or inactivation of both *NF1* alleles.³⁰ Café au lait macules, in particular, can occur in a variety of syndromes other than NF-1; thus, their detection in an infant or young child does not signal the need for extensive neurodiagnostic imaging in the absence of other clinical stigmata or a family history of NF-1, but it does warrant conscientious pediatric follow-up. Similarly, Lisch nodules simply represent melanocytic iris hamartomas; although these lesions increase in frequency during childhood and are present in more than 90% of affected patients by the completion of puberty,^{17,31} they do not interfere with vision.

In contrast, skeletal manifestations can be of major long-term functional significance. Congenital bowing and/or dysplasia of the long bones, particularly the tibia, may lead to pathologic fractures that resist healing.^{14,32} Osseous dysplasia can involve the sphenoid bone as a congenital or acquired process,³³ which leads to herniation of the temporal lobe contents into the orbit and, in some cases, produces pulsatile proptosis and seizures (► Fig. 48.1). Because few patients exhibit progressive

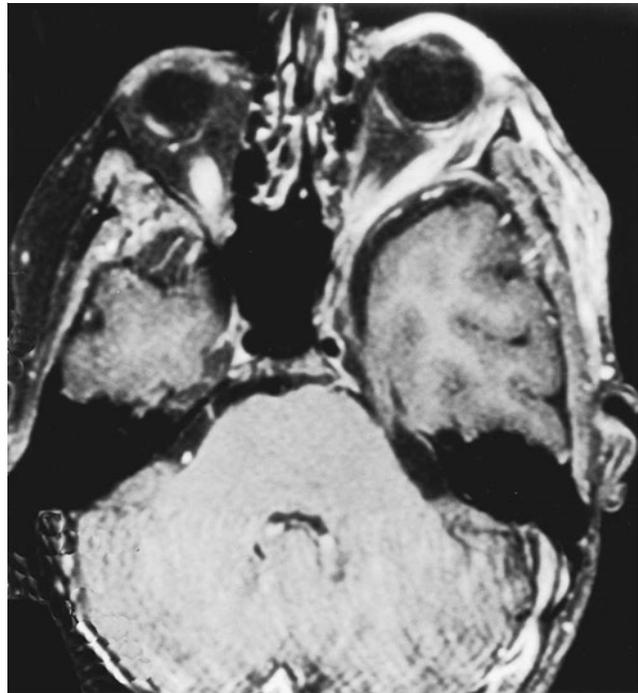

Fig. 48.1 This axial T1-weighted magnetic resonance image shows left sphenoid dysplasia with protrusion of the temporal dura into the posterolateral orbit and resultant proptosis.

impairment from this deformity, operative intervention should be limited to those children with worsening proptosis in the absence of another explanation, such as an orbital plexiform neurofibroma, or with intractable seizures from the involved temporal lobe. In such rare cases, reconstruction with split-thickness calvarial grafts or rib grafts may be beneficial.

Spinal manifestations are also common, even in the absence of neoplastic involvement. Some degree of scoliosis is present in most patients with NF-1,^{14,32} but it often does not require specific therapy. However, in a small percentage of children with NF-1, the scoliosis is severe and rapidly progressive. Because many of these patients will be found to have an intra- or extra-axial neurofibroma, which may need to be addressed in conjunction with a spine-straightening procedure, MR imaging is an essential step in the preoperative evaluation. Regardless of the cause for the scoliosis, the rapid progression that occurs in some children mandates that vigilant follow-up and expeditious intervention be pursued to avoid severe deformity. Patients often require a combination of bracing, anterior and posterior fusion, and instrumentation to treat this problem. In such cases, the use of MR imaging-compatible hardware is advisable because these patients generally require long-term surveillance for tumor growth. Other, less serious spinal manifestations include vertebral scalloping and nonneoplastic widening of the neural foramina from dural ectasia.³⁴ Most cases require no specific intervention. An additional phenomenon that is occasionally observed in patients with NF-1 is segmental hypertrophy.⁵ This may involve a portion of the head or one of the extremities. Although there is usually an underlying neoplastic component in the involved area, the deformity often exceeds that directly attributable to the tumor. It remains uncertain

whether this reflects generalized mesenchymal dysplasia in the involved area or a combination of neurogenic and humoral factors initiated by the tumor. Children with NF-1 have also been noted to have an increased incidence of central precocious puberty and growth hormone deficiency; in some cases, this is independent of any radiologically apparent hypothalamic tumor involvement.

In addition to the nervous system tumors discussed below, patients with NF-1 are also at risk for a variety of systemic malignancies, including leukemia, pheochromocytoma, rhabdomyosarcoma, adenocarcinoma of the ampulla of Vater, melanoma, and non-Hodgkin lymphoma, presumably reflecting either loss or inactivation of the second *NF1* allele or other secondary genetic events.^{5,35,36}

Neurofibromatosis 2

In patients with NF-2, the major serious nonneural manifestation is the development of posterior subcapsular cataracts, which are detected in 85% of affected individuals and often progress with age.¹² Because these lesions can threaten vision, conscientious ophthalmologic follow-up is required, and surgical removal of the cataract may be indicated. In patients with unilateral visual loss secondary to one of these lesions, particular attention must be directed to monitoring and protecting vision in the contralateral eye, which includes preserving facial nerve function to maintain eye closure and corneal protection.

48.2.2 Neurologic Manifestations

Children with either NF-1 or NF-2 may present with neoplasms of the brain, spinal cord, and peripheral nerves, but the most common types of lesions differ significantly in these two syndromes. In addition, patients with NF-1 may exhibit a variety of nonneoplastic neurologic manifestations that must be distinguished from tumors to avoid unnecessary intervention. The most common processes are summarized below, along with management approaches.

Neurofibromatosis 1

Focal Areas of Increased Signal on T2-Weighted Magnetic Resonance Imaging

By far the most common abnormalities on MR imaging in patients with NF-1 are foci of increased signal on T2-weighted images without mass effect or contrast enhancement, so-called unidentified bright objects (UBOs; ▶ Fig. 48.2). These foci, which are detected in 60 to 80% of children with NF-1,^{37,38} may be solitary, multiple, or confluent and are seen most commonly in the basal ganglia, internal capsule, brainstem, and cerebellum. In view of the high frequency of these lesions in patients with NF-1, it has been suggested that their presence be added to the diagnostic criteria for this syndrome. On serial images in individual patients, foci of T2 signal abnormality often increase in frequency and number early in childhood, then regress later in childhood.^{37,38} This pattern suggests that these lesions represent age-related abnormalities in myelination. Some groups have noted that the presence and extent of these signal abnormalities correlate with the detection of learning disabilities,

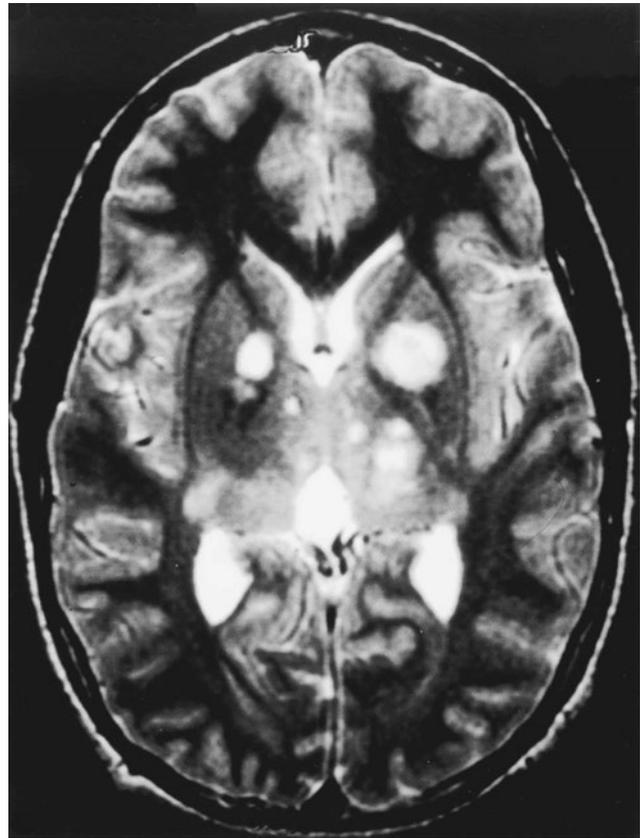

Fig. 48.2 This axial T2-weighted magnetic resonance image demonstrates the characteristic areas of T2 signal abnormality that are commonly detected within the basal ganglia and occasionally within the cerebellum and other regions of the brain in patients with neurofibromatosis type 1.

which are encountered in at least 25% of patients with NF-1, although others have failed to note a clear relationship.^{28,29} Similarly, it remains uncertain whether patients with UBOs are at increased risk for the development of central nervous system neoplasia compared with patients who have NF-1 without this finding, although at least one group has noted such a trend.³⁹

Because UBOs themselves typically follow a benign course, their detection in an otherwise asymptomatic child does not signal the need for serial MR imaging. However, this conservative follow-up approach should not be applied to childhood lesions that exhibit atypical MR imaging features, such as mass effect or enhancement, or that are associated with focal neurologic symptoms. Such a follow-up approach should also not be followed in older patients with new lesions. In all these instances, the natural history remains uncertain.

Optic Pathway Lesions

The second most common imaging abnormality in NF-1 is optic pathway glioma, detected in at least 15% of patients (▶ Fig. 48.3). Several characteristic lesion types may be seen. The mildest abnormalities consist only of thickening of one or both optic nerves⁴⁰; although most such lesions are low-grade gliomas, others may simply represent hyperplasia of the optic nerve sheath. Other patients exhibit a globular thickening of

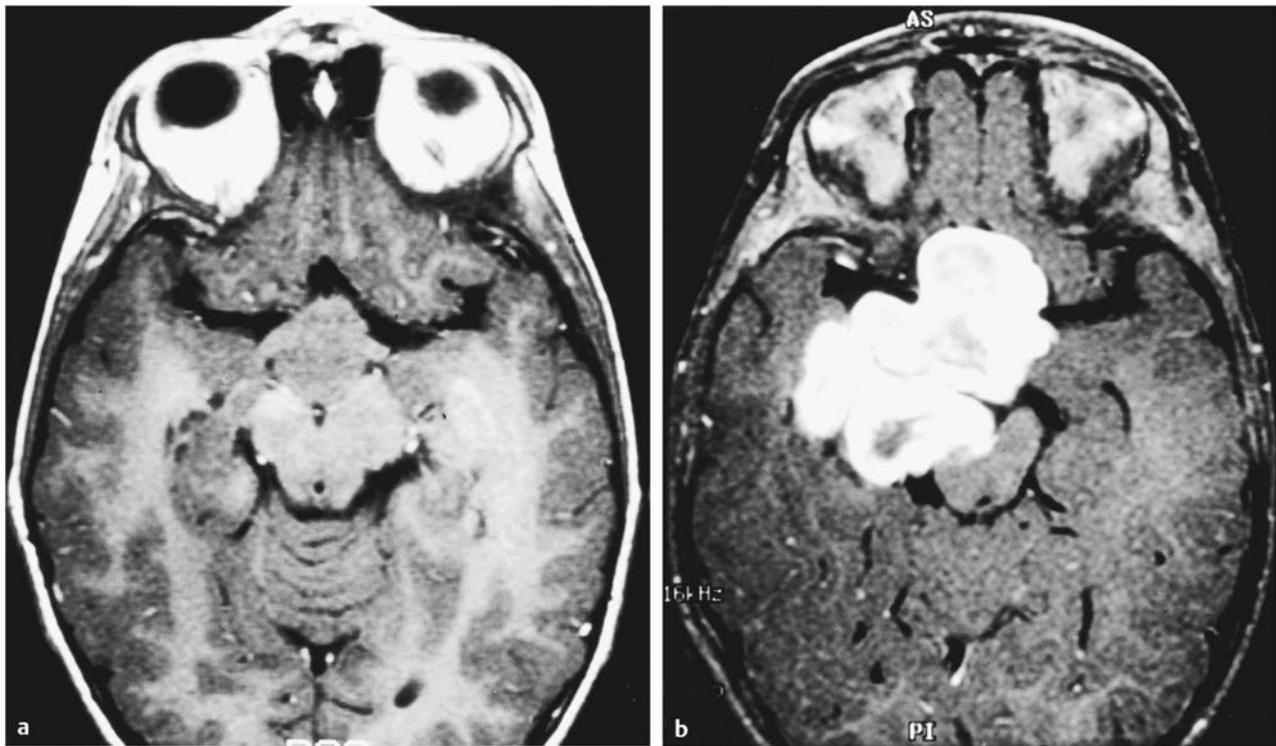

Fig. 48.3 Two magnetic resonance images that illustrate the diverse manifestations of optic–hypothalamic gliomas in patients with neurofibromatosis type 1. (a) Globular enlargement of the optic chiasm is depicted. In this patient, T2 signal abnormality was seen along the optic tracts bilaterally. (b) A massive chiasmatic–hypothalamic glioma shows bright enhancement with intravenous contrast.

the optic nerves and chiasm (► Fig. 48.3a) that may occur in conjunction with T2 signal abnormalities streaking backward along the optic pathways and upward into the hypothalamus. Biopsy of such lesions has generally confirmed the presence of a low-grade glioma.^{41,42} Finally, a small percentage of patients present with a large mass lesion involving the optic chiasm and hypothalamus that may extend upward into the third ventricle, laterally into the temporal fossa, anteriorly beneath the frontal lobe, and posteriorly into the perimesencephalic region (► Fig. 48.3b).

The optimal management for such lesions remains controversial. Before the era of MR imaging and high-resolution computed tomography (CT), optic pathway tumors were generally detected only after the onset of visual impairment, hypothalamic dysfunction, or symptoms of increased intracranial pressure (ICP), which occur in a small percentage of patients and clearly mandate therapeutic intervention. However, most lesions are now detected in asymptomatic individuals in whom the natural history and the indications for intervention are less clear.

Several studies have reported the results of expectant management in patients with NF-1 who had optic pathway tumors that were asymptomatic or minimally symptomatic in association with mild visual loss or precocious puberty.^{41–43} Listernik et al⁴³ noted that only 3 of 33 asymptomatic or minimally symptomatic patients with optic pathway tumors exhibited progressive tumor growth or deteriorating vision after diagnosis, with a median follow-up of 2.4 years. Other groups have also noted that optic gliomas in children with NF-1 have a

distinctly more indolent course than in children without this disorder,^{44,45} although a sizeable subset do progress radiologically and in terms of visual loss.^{46,47} Thus, although the detection of an initially asymptomatic or minimally symptomatic optic pathway lesion on screening MR imaging does not signal the need for immediate intervention, ongoing imaging surveillance is prudent until the natural history can be established conclusively.

However, the role of routine imaging as a screening test remains controversial because most optic pathway lesions in patients with NF-1 are asymptomatic and show a low frequency of significant enlargement, at least in the span of several years.⁴⁸ Several groups have recommended annual MR imaging studies in young children with NF-1. Others have limited imaging to patients with new or progressive symptoms and signs, such as nystagmus, strabismus, visual loss, visual field deficits, precocious puberty, growth delay, diencephalic syndrome, headache, and other symptoms of increased ICP; they recommend following the remaining patients with annual clinical evaluations and ophthalmology examinations.

One drawback to the latter approach is that in children younger than 5 years, deterioration becomes apparent only when impairment is far advanced because objective testing of vision is difficult in these young patients. Accordingly, we often obtain a baseline imaging study in children with NF-1 who are younger than 5 years of age, after which time a thorough ophthalmologic evaluation can generally be performed. Subsequent MR imaging studies are performed only in children with newly diagnosed or progressive visual impairment and in those with

significant abnormalities on initial MR imaging that do not merit immediate treatment, particularly if the children are still too young to cooperate with a thorough ophthalmologic examination. We no longer routinely image older children and instead prefer annual or semiannual clinical evaluations, which include testing of visual acuity and fields as well as a general physical and neurologic examination, with attention directed toward looking for signs of neuroendocrine impairment. The value of visual evoked potential testing for identifying patients with subtle visual impairment from optic gliomas, who may be most likely to benefit from a detailed imaging examination, remains controversial.

However, the aforementioned guidelines do not apply to those children who present with severe visual impairment. In our experience, patients who exhibit significant visual compromise have a high risk for further visual deterioration and require either very close follow-up (e.g., every 3 months) or immediate therapy. These recommendations also do not apply to children who have sizeable, symptomatic lesions on their initial imaging studies because these patients generally require immediate intervention.

Symptomatic optic nerve gliomas in patients with NF-1 have in the past been suggested to have a less favorable prognosis for long-term disease control after surgical resection than comparable lesions in patients without NF-1⁴⁹; however, this probably reflects an artifactual inference in studies conducted in the era before MR imaging, given that a lesion that is truly localized to one optic nerve is uncommon in NF-1 and that unilateral treatment of a bilateral process is unlikely to have long-term efficacy. In more recent studies, symptomatic chiasmatic–hypothalamic tumors in patients with NF-1 actually appear to carry a *more favorable* prognosis for long-term disease control than comparable tumors in patients without NF-1.^{41,42,44,45,50} For example, Hoffman et al⁴¹ noted that whereas only 1 of 23 patients with NF-1 and optic–hypothalamic glioma died of disease progression, 7 of 39 patients without NF-1 died ($p = 0.045$). Deliganis et al⁵⁰ also noted that time to progression among children with newly diagnosed symptomatic optic pathway gliomas arising in association with NF-1 was substantially longer than that for patients with sporadic tumors (8.4 years vs. 2.4 years, respectively). After an average follow-up of 10.2 years, only 5 of 16 patients with NF-1 exhibited disease progression.⁵⁰ In addition, a subset of tumors will exhibit spontaneous regression in the absence of any surgical or adjuvant therapy.⁵¹

With increased understanding of the natural history of optic pathway lesions in patients with NF-1, the indications for surgical intervention have narrowed considerably. Because the histologic identity of a given lesion is rarely in doubt, biopsy for purely diagnostic reasons is generally not needed. In the occasional patient with an optic nerve glioma that is clearly unilateral, in whom proptosis and blindness are apparent, surgical resection of the involved nerve from the globe to the chiasm may be considered. Such cases are rare because the majority of patients are found on MR imaging also to have involvement of the chiasm and contralateral optic nerve. In these children, radiotherapy or chemotherapy, both of which are described in detail below, may be preferable. These patients should also be distinguished from the occasional patient with an orbital plexiform neurofibroma that extends backward from the globe toward the anterior cavernous sinus, in whom radical resection of the

lesion may be required. Surgery has also been advocated for children with large tumors growing exophytically from the optic chiasm.^{41,52} However, it remains uncertain whether the long-term results in terms of disease stability and functional outcome that are achieved with aggressive resection represent an improvement over those obtained with nonsurgical approaches.⁵³

In contrast to the tumors described above, for which surgical intervention may have a role, albeit a controversial one, the majority of optic pathway gliomas are clearly not candidates for excision because of their diffuse involvement of the optic apparatus and hypothalamus. Radiation therapy has historically been used in the treatment of these unresectable lesions, and it provides excellent results in terms of disease stabilization and occasionally regression, often leading to significant improvement in visual function.^{54,55} However, radiation may result in severe cognitive and endocrine deficits^{56,57} and places the patient at risk for radiation-induced malignancies⁵⁸ and vasculopathy, such as moyamoya syndrome.⁵⁹

Accordingly, chemotherapy has come to assume an increasing role in the management of these tumors, particularly in patients younger than 5 to 10 years,^{44,60,61} in whom the risks for long-term radiotherapy-induced cognitive and endocrine impairment are particularly high and in whom the potential benefits of avoiding, or at least deferring, radiotherapy are substantial. A variety of regimens have been employed, with response rates of 20 to 80% and response or stabilization rates of 75 to 100%.^{44,60,61} The efficacy of a carboplatin/vincristine regimen in children with low-grade gliomas associated with NF-1 was recently assessed in detail in the Children's Oncology Group 9952 study, in which the results in terms of disease control appeared to be superior to those in children with low-grade gliomas not related to NF-1.¹⁰⁸ Although children with NF-1 do not appear to differ significantly from those without NF-1 in terms of their response to chemotherapy,⁶⁰ concerns about their potentially increased risk for secondary leukemias resulting from alkylating agents have provided a rationale for avoiding agents like nitrosoureas and temozolomide in front-line regimens. New molecularly targeted agents directed against NF1-related signaling pathway alterations may provide a preferable future alternative for these tumors.

Cerebral and Cerebellar Hemispheric Gliomas

A small percentage of patients with NF-1 develop enlarging lesions within the cerebral (► Fig. 48.4a) and cerebellar (► Fig. 48.4b) hemispheres that differ in appearance from UBOS. The majority of such lesions are gliomas, which exhibit local mass effect and decreased signal on T1-weighted images with enhancement that may be uniform, ringlike, in the form of a mural nodule, or absent altogether. Most lesions are benign and amenable to complete or nearly complete resection, although a small percentage are malignant. Various intraoperative adjuncts, such as stereotactic guidance, intraoperative imaging, and functional monitoring (described more fully in Chapter 34) have allowed resection of deep-seated lesions with acceptable morbidity.

Postoperative management is guided by the histopathologic diagnosis. Low-grade gliomas are managed expectantly after a radiographically complete resection and, in some cases, after extensive subtotal resection. In patients with substantial

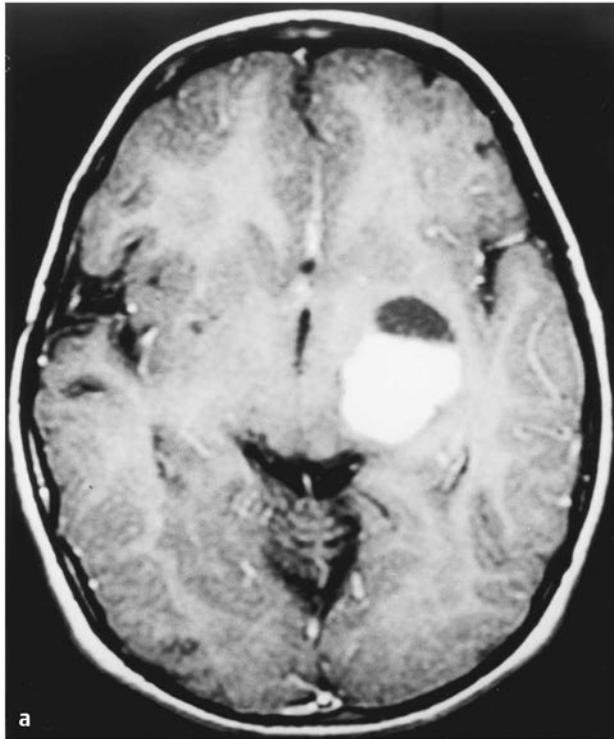

Fig. 48.4 Magnetic resonance images of (a) deep cerebral and (b) cerebellar enhancing lesions in patients with neurofibromatosis 1. Both lesions were detected on follow-up imaging evaluations after the results of initial studies obtained several years earlier had been negative. The patient depicted in (a) had undergone resection of an optic-hypothalamic glioma 8 years previously. Because these lesions had enlarged progressively, complete resection was undertaken. In both cases, low-grade astrocytoma was detected histopathologically.

unresectable disease or those in whom the tumor recurs after an initial resection, adjuvant radiotherapy or chemotherapy is performed as outlined above. In carefully selected patients with well-localized unresectable disease, stereotactic radiosurgery may have a therapeutic role after disease progression.⁶² This approach minimizes exposure of the surrounding brain to radiation, which is an important consideration in patients with NF-1, in whom multiple brain tumors may develop during their lifetime, although we have anecdotally observed an enhanced tendency to radiation swelling in comparison with children who do not have NF-1.

Patients with NF-1 in whom malignant gliomas develop are managed in the same fashion as patients without NF-1, in the absence of any data that these two groups differ prognostically. Specifically, after an attempt at maximal surgical resection, a combination of involved-field radiotherapy and chemotherapy is administered to patients older than 3 years. Younger children are treated with chemotherapy initially in the hope of deferring irradiation for as long as possible. A variety of chemotherapeutic regimens have been studied in cooperative group and limited institution trials, with some evidence of efficacy,⁶³ although the optimal combination of agents remains uncertain. Unfortunately, even with maximal therapy, the majority of affected patients die of progressive disease.

Brainstem Gliomas

Brainstem gliomas in patients with NF-1 are a heterogeneous group that in many ways differ biologically from comparable lesions in patients without NF-1. The most common abnormality is a diffuse area of brainstem enlargement associated with increased signal on T2-weighted images^{38,64} (► Fig. 48.5). Although such lesions have been grouped in some reports with UBOs, their appearance and behavior are distinctive for several reasons. Not only are they substantially larger than typical UBOs, but they also often produce definite mass effect and exhibit abnormal signal on T1-weighted images. Finally, these lesions do not regress over time and are often associated with mild focal neurologic deficits. Their histopathologic basis is problematic. Those tumors that have been biopsied have been found to be low-grade gliomas,⁶⁵ and their generally benign behavior mandates a correspondingly conservative approach to therapy. Thus, although the lesions may in some ways resemble diffuse intrinsic tumors in patients without NF-1, their prognosis generally differs drastically from that of these biologically malignant lesions. Biopsy and adjuvant therapy (or the institution of empiric adjuvant therapy, as is typically done for diffuse brainstem gliomas not associated with NF-1) should be limited to the occasional patient who does show clear clinical and/or

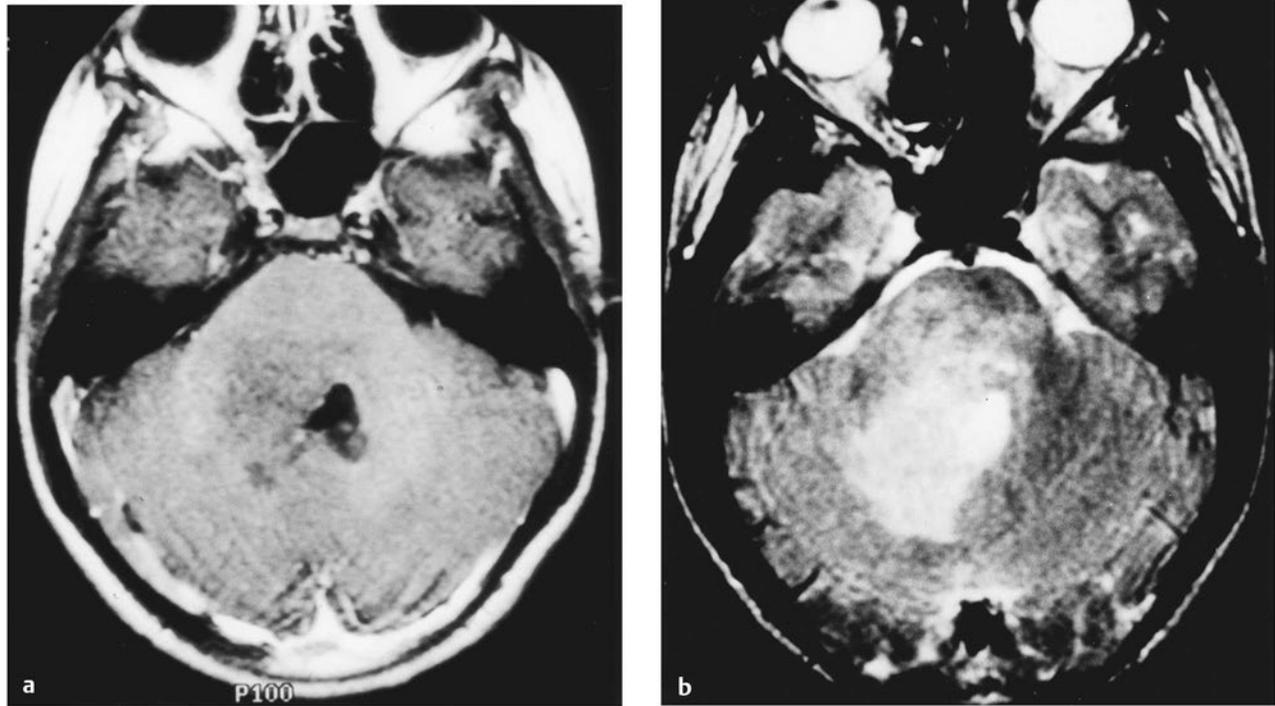

Fig. 48.5 These magnetic resonance images demonstrate a common imaging abnormality in patients with neurofibromatosis 1 (NF-1). The brainstem is diffusely enlarged with (a) decreased T1 signal intensity and (b) increased T2 signal over a wide area centered at the cerebellar peduncle, in some ways resembling the appearance of diffuse intrinsic tumors in patients without NF-1. This patient, shown here at 16 years of age, initially manifested with a right facial paresis and dysarthria secondary to palatal insufficiency at age 4. No imaging evidence of tumor progression was detected during a follow-up interval of 12 years.

radiographic progression.⁶⁶ We do, however, advocate close follow-up imaging of such children until the biological behavior of the lesions can be confirmed because a small percentage will indeed progress.

A second group of brainstem lesions in patients with NF-1 are focal enhancing nodules with or without associated cystic areas.⁶⁴ The biological behavior of these lesions is generally indolent but, ultimately, unpredictable. We have undertaken treatment in those children in whom progressive tumor enlargement was associated with significant local mass effect or with the development of progressive clinical symptoms. Although we have observed small, focal intrinsic lesions to enlarge progressively and asymptotically during adolescence and then regress spontaneously without treatment, exophytic tumors seem to follow a more aggressive course and often require treatment. Such tumors are frequently pilocytic astrocytomas or gangliogliomas, and in some cases they may have anaplastic features. Because the natural history of such lesions remains uncertain, we perform routine follow-up imaging, even in those children who are managed conservatively.

A final group of brainstem lesions in patients with NF-1 are periaqueductal gliomas (► Fig. 48.6). These lesions typically manifest with late-onset aqueductal stenosis and are presumed to be low-grade gliomas, although biopsy confirmation has (appropriately) been limited.^{64,67} The tumors exhibit an indolent course and may remain quiescent for years without intervention, or

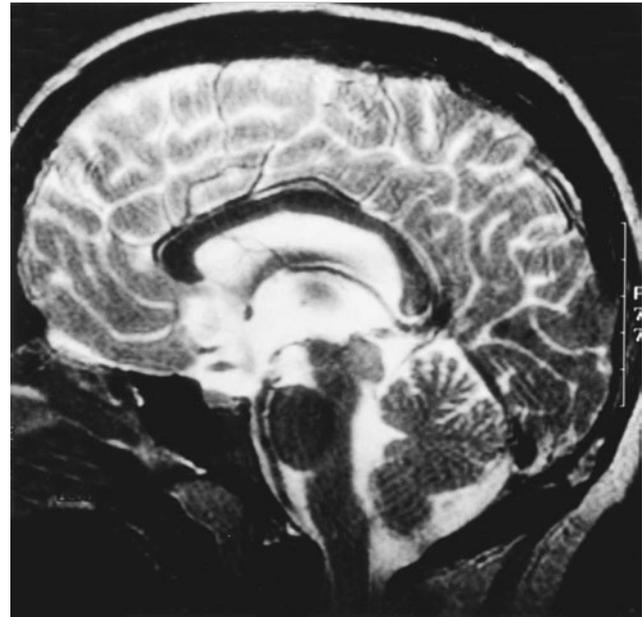

Fig. 48.6 This sagittal T2-weighted magnetic resonance image demonstrates a benign tectal tumor in a child with neurofibromatosis 1 that has remained stable in size for 10 years without specific treatment other than a third ventriculostomy.

they may manifest with obstructive hydrocephalus, in which case treatment with cerebrospinal fluid diversion, ideally third ventriculostomy, is warranted. We typically perform follow-up imaging on a yearly basis for 5 years and periodically thereafter, reserving biopsy and/or adjuvant therapy for lesions that enlarge or produce progressive symptoms.

Neurofibromas

Paraspinal and peripheral neurofibromas are one of the hallmarks of NF-1 and are observed in most patients. These lesions exhibit loss or inactivation of the second *NF1* allele in Schwann cells already harboring an *NF1* mutation or deletion.^{68,69} Although the tumors have been categorized in the past with neurilemmomas, which are the hallmarks of NF-2, the two groups of tumors are readily distinguished on histologic analysis. Neurilemmomas characteristically exhibit alternating areas of cellular (Antoni A) architecture with palisading spindle cells that orient into Verocay bodies and Antoni B architecture comprising a loose array of spindle cells in a mucinous background. In contrast, neurofibromas are composed of spindle cells in a myxomatous stroma that incorporates myelinated and unmyelinated axons, which are rarely seen in neurilemmomas (► Fig. 48.7).

Neurofibromas are best demonstrated on MR imaging, which is useful for delineating the relationship between the tumor, surrounding nerve(s), and adjacent structures. For patients with paraspinal lesions, this study provides information about the extent of foraminal and intraspinal encroachment; for those with visceral lesions, it provides information about the relationship between the tumor and surrounding critical structures. Based on the imaging appearance, the lesions may be categorized by their pattern of growth as fusiform neurofibromas, which are discrete lesions that involve a circumscribed area of a nerve, or plexiform neurofibromas, which exhibit diffuse involvement of a broad extent of one or more nerves.⁷⁰

From a diagnostic and therapeutic standpoint, neurofibromas are often categorized by location as subcutaneous neurofibromas, peripheral nerve neurofibromas, plexus neurofibromas,

paraspinal neurofibromas, craniofacial neurofibromas, or visceral neurofibromas. *Subcutaneous neurofibromas* may occur as isolated, fusiform lesions or as plexiform growths arising from a group of tiny cutaneous nerves. They usually begin as raised subcutaneous masses that may enlarge and become pedunculated over time. Although the tumors may be removed, this is not practical as a rule because new lesions are likely to grow soon. Nonetheless, in selected cases, resection of one or more lesions may be beneficial to the patient's self-esteem, particularly if a cosmetically significant site is involved. Resection is also indicated for lesions that are painful, enlarging rapidly, or arising in an area prone to irritation, such as the belt line. Because a small percentage of these tumors will become malignant, patients should be encouraged to report lesions that enlarge rapidly, become red or ulcerated, or that cause progressive discomfort, because excisional biopsy may be indicated.

Peripheral Nerve Neurofibromas

If symptomatic, peripheral nerve neurofibromas produce neurologic dysfunction in the distribution of a major nerve trunk, with pain and paresthesias that often are initiated or exacerbated by manipulation of the involved nerve (► Fig. 48.8).⁷⁰ Unlike neurilemmomas, which typically involve a single fascicle of a major nerve, with the other fascicles splayed over the tumor capsule, neurofibromas often involve many or all of the fascicles of a nerve. In many cases, this limits their resectability; however, in some instances, it is possible to resect multiple involved fascicles without sacrificing significant neural function. This approach is facilitated by beginning the dissection at the proximal and distal poles of the tumor and identifying the fascicle(s) from which the tumor arises, which may then be sacrificed. Intraoperative nerve stimulation techniques are essential for confirming that the fascicles to be sectioned are indeed non-functional. In some cases, complete resection is not feasible without risking neurologic impairment, and a subtotal resection must be pursued. In these instances, the residual tumor must be followed for evidence of further growth or malignant changes,⁷¹ which often manifest with rapid lesion growth, pain,

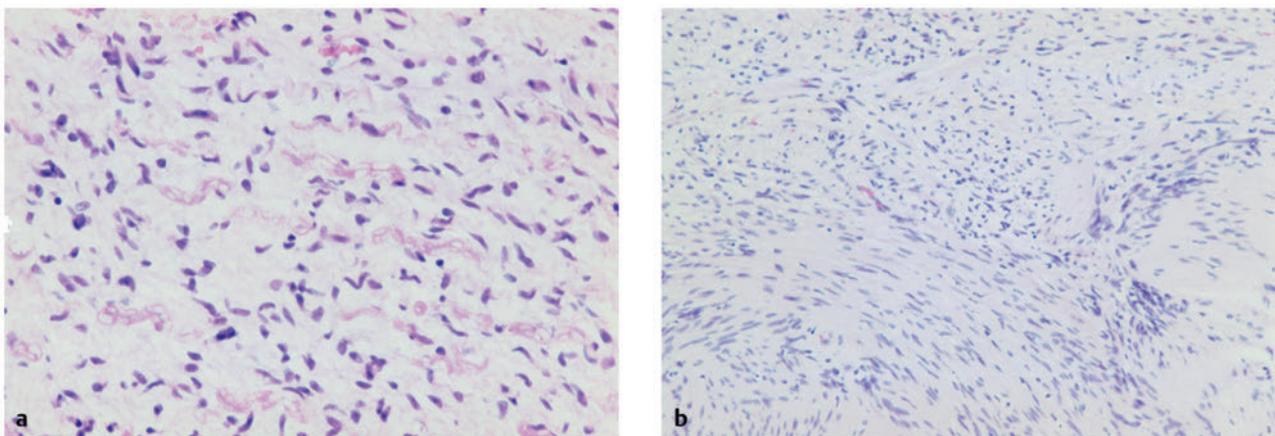

Fig. 48.7 Hematoxylin and eosin--stained paraffin sections of (a) a neurofibroma and (b) a neurilemmoma. Neurofibromas typically exhibit a chaotic array of spindle cells that encompass myelinated and unmyelinated nerve fibers, whereas neurilemmomas characteristically exhibit alternating areas of palisading nuclei and intervening cytoplasm (Verocay bodies) that rarely contains intervening axons.

Fig. 48.8 This magnetic resonance image shows a peripheral neurofibroma in the right median nerve that caused progressive radicular pain and paresthesias exacerbated by direct percussion. The tumor arose from a single fascicle and was amenable to complete resection.

and ulceration. In addition, malignant lesions typically exhibit inhomogeneity and irregular enhancement on MR imaging, whereas benign neurofibromas show uniform enhancement.⁷² For lesions that exhibit malignant features, the operative and postoperative management strategy must involve a multidisciplinary approach incorporating neurosurgical, general surgical, orthopedic, medical oncology, and radiation oncology input.⁷¹

Total resection is inherently infeasible for plexiform tumors, which are nonencapsulated and infiltrate extensively along and within involved nerves. Although en bloc resection and grafting are theoretically possible if only one nerve is involved, the functional results of this approach have been poor. Complete resection is rarely an option for lesions that involve the brachial plexus or lumbosacral plexus, and it is usually reserved for cases with malignancy and those in which pain or compression of surrounding structures leads to intolerable symptoms. Because plexiform lesions may exhibit indolent behavior, aggressive intervention should be limited to tumors causing progressive impairment. Such patients may be appropriate candidates for investigational chemotherapy protocols. Studies of 13-*cis*-retinoic acid, interferon- α , thalidomide, farnesyltransferase inhibitors, and Raf kinase inhibitors have suggested efficacy in terms of stabilizing previously progressive disease, although

objective disease regression is infrequent.^{73,74} The erratic growth of plexiform neurofibromas, as well as their complex geometry, has complicated efforts to establish conclusively that these agents modify the natural history of the tumors.^{75,76} The development of genetically engineered tumor models for NF-1 has provided an opportunity to examine novel therapeutic strategies preclinically, which it is hoped will improve the pace of identifying and prioritizing novel approaches targeted against growth signaling pathways.⁷³

Paraspinal Neurofibromas

Paraspinal neurofibromas are usually fusiform tumors that typically involve nerve roots at their entry into the spinal canal (► Fig. 48.9).⁷⁷ In some cases, virtually every nerve root from the cervical to the sacral spine is involved (► Fig. 48.9a). Because most lesions enlarge slowly, if at all, intervention is reserved for those tumors that show progressive encroachment on the spinal canal with resultant neural compromise (► Fig. 48.9b). These lesions are typically approached with a laminotomy for the intraspinal component. The extraspinal component may be removed transforaminally if the tumor is small and medially located, but larger lesions require a more laterally directed approach. A large extraspinal component of a cervical lesion can be removed with an extreme lateral approach or modifications thereof, with care taken to avoid injury to the vertebral artery.⁷⁸ Thoracic lesions may be removed with a costotransversectomy, lateral extracavitary, or transthoracic intra- or extrapleural approach, depending on the size of the lesion.⁷⁹ Lumbar lesions are usually removed with a retroperitoneal approach, potentially combined with a posterior approach. Resection of the involved nerve root is often required to obtain complete tumor removal; this can sometimes be accomplished without producing severe neurologic impairment, although neuromonitoring techniques are helpful in making this determination and guiding safe resection extent. Because of the aforementioned predisposition of children with NF-1 to the development of scoliosis, patients must be followed with serial clinical and radiographic evaluations for evidence of progressive postoperative deformity,⁸⁰ which is best treated before it reaches an advanced stage.

Craniofacial Neurofibromas

Craniofacial neurofibromas are generally plexiform growths that involve peripheral nerves of the face, orbit, and cranial base. Facial lesions are generally treated by plastic surgeons; the major neurologic issue is the potential for facial or trigeminal nerve compromise resulting from compression by the tumor or injury during tumor resection. Orbital lesions present a major cosmetic and functional challenge because they often produce proptosis, strabismus, and visual compromise. These lesions can also extend intracranially into the cavernous sinus and are rarely resected completely without sacrificing the globe; hence, surgery is reserved for patients with advanced visual loss and unremitting tumor growth.⁸¹ In patients with intact vision, functional stabilization can often be achieved by partial tumor resection because the residual lesion will sometimes fail to grow.

Visceral Neurofibromas

Visceral neurofibromas (► Fig. 48.10) also constitute a challenging management problem because they are usually plexiform

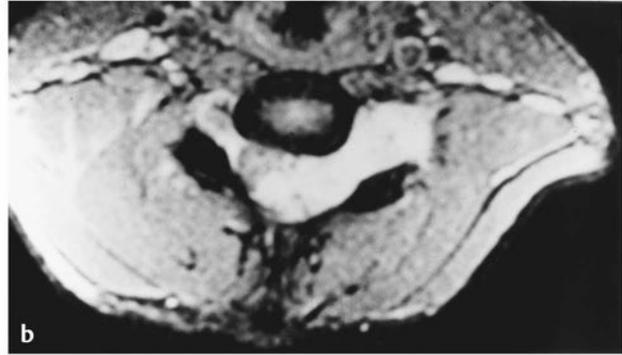

Fig. 48.9 Magnetic resonance images. (a) Multisegmental involvement of the exiting spinal nerve roots by neurofibromas in an 11-year-old boy. These lesions caused no intraspinal compression and have remained stable for more than 8 years without intervention. (b) Intraspinal growth of one of several paraspinal neurofibromas in an 18-year-old boy caused a mild, progressive Brown-Séquard syndrome. This lesion was resected completely, and the patient remains free of disease progression.

Fig. 48.10 Magnetic resonance image of a rapidly enlarging plexiform neurofibroma in a 7-year-old girl involving the left brachial plexus, thoracic cavity, and parapharyngeal region from the chest to the skull base, producing moderate tracheal compression and enveloping the great vessels of the neck. The patient presented with myelopathy and radiculopathy from an associated intraspinal tumor component, which was resected. The extraspinal component stabilized after the initiation of chemotherapy with interferon- α .

tumors that cannot be completely removed and pose a long-term risk for progressive impairment and malignant transformation. Subtotal resection is often indicated to relieve pulmonary compromise (from large intrathoracic lesions), upper airway obstruction (from parapharyngeal neurofibromas), abdominal discomfort, or spinal cord compression (from foraminal encroachment of a paravertebral tumor). Like other unresectable plexiform neurofibromas, these tumors are appropriate candidates for chemotherapy trials.

Neurofibromatosis 2

Vestibular Neurilemmomas

Tumors of the eighth cranial nerve occur in most patients with NF-2 and often become symptomatic in adulthood, where they are beyond the scope of pediatric neurosurgical practice. However, occasional lesions are detected earlier in childhood (► Fig. 48.11), particularly as a consequence of advances in neuroimaging coupled with the proactive screening of children of affected adults.^{18,82} The finding in a child of a posterior cataract or multiple spinal cord or peripheral nerve tumors, without Lisch nodules, café au lait macules, or an alternative explanation, should raise concern about an underlying diagnosis of NF-2, and such children should undergo an MR imaging examination of the head for intracranial manifestations of NF-2. The development of symptomatic tumors in childhood tends to indicate a more aggressive course in comparison with that of older patients who have this disorder.⁸³⁻⁸⁵

Although there is general agreement that MR imaging is the optimal screening tool for vestibular neurilemmomas in

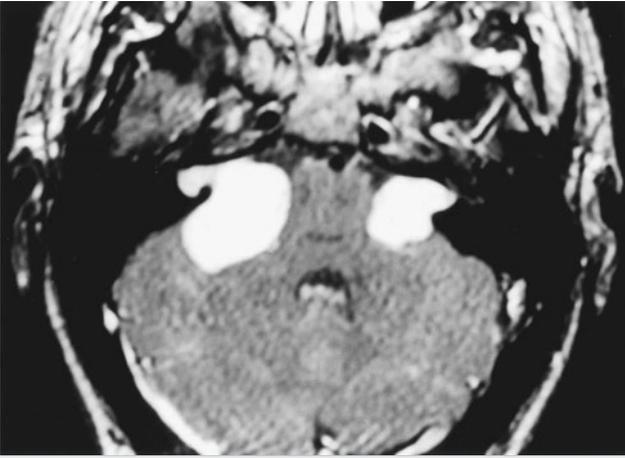

Fig. 48.11 Magnetic resonance image of bilateral vestibular neurilemmomas in the 16-year-old son of a woman with known neurofibromatosis 2. On initial examination, he was noted to have unilateral blindness from a posterior cataract and right-sided deafness that reportedly had developed insidiously. The larger, right-sided vestibular lesion was resected uneventfully, and the left-sided lesion was observed while the patient learned sign language and lip reading.

Fig. 48.12 Magnetic resonance image of a foramen magnum meningioma in a child with neurofibromatosis 2 that manifested with neck pain and ataxia; the lesion was completely resected.

individuals at risk for NF-2 and that periodic hearing tests are indicated for the functional evaluation of these patients, the indications and preferred approaches for the treatment of these lesions, once detected, remain controversial. Their natural history is variable, although the majority of patients will show progressive tumor enlargement and hearing deterioration over time, which can be apparent even between annual evaluations and may differ between the two ears in patients with bilateral lesions.⁸⁶ The primary management goal is the preservation of function, but the best way for achieving this outcome is uncertain. In a patient with a large lesion causing significant brainstem compression, the decision to proceed with surgical resection is relatively clear. However, for patients with relatively small, asymptomatic lesions, the optimal approach is less obvious. Some surgeons recommend early attempts at radical tumor resection based on the view that this approach has the greatest likelihood for preserving hearing postoperatively.^{87,88} However, the risks for iatrogenic hearing loss are all “up front” and pose a major concern in a patient with functional hearing in whom tumor- or treatment-induced deafness in the contralateral ear is a significant long-term risk. Among those who favor early surgery, some recommend removing the larger of two lesions, with the thought that this lesion is most likely to pose an initial threat of ipsilateral hearing loss. Others, however, advocate removing the smaller lesion, which theoretically affords the patient the best chance of achieving both tumor removal and ipsilateral hearing preservation. Tumor resection is sometimes combined with placement of a cochlear or auditory brainstem implant, which may provide a way for ensuring at least some hearing preservation in patients with bilateral tumors who undergo surgical intervention.^{89,90}

However, an equally cogent argument can be made for deferring surgery until there is objective evidence of tumor progression or hearing loss. Because of the variable natural history of these lesions, the detection of bilateral vestibular nerve tumors in a patient with NF-2 does not necessarily imply that either lesion is going to immediately threaten hearing.^{19,91} Stereotactic radiosurgery provides an alternative approach for the treatment of such lesions.^{92,93} It is uncertain whether the chances for long-term hearing preservation are any better than with open resection; however, hearing loss, if it occurs after radiosurgery, typically develops in a delayed fashion. This interval provides the patient time to learn sign language and lip reading. Another approach that has been advocated in patients with bilateral tumors is subcapsular resection of the lesion, leaving a small amount of tumor adherent to the facial and acoustic nerves to minimize the risk for nerve injury.⁹⁴ In the absence of objective data to support one management approach versus another, we believe that therapeutic decision making should be individualized, with the risk tolerance of the patient and family taken into account, after the various management approaches with their pros and cons have been thoroughly discussed. Because of the complexity of the management issues involved, a supraregional approach to the care of affected patients has been advocated to optimize functional outcome.⁹⁵ More recently, pharmacologic approaches have been explored for these tumors, particularly bevacizumab, which has demonstrated tumor regression, although the applicability of this agent for long-term disease control remains to be defined.⁹⁶⁻⁹⁸

Intracranial Meningiomas and Nonvestibular Cranial Nerve Neurilemmomas

More than 30% of patients with NF-2 have multiple nonvestibular neurilemmomas, and approximately half have meningiomas (► Fig. 48.12).^{82,99} For reasons that are unclear, symptomatic meningiomas in these young patients follow a more aggressive course than do those arising in adults with NF-2.¹⁰⁰ It has been suggested that a distinct subgroup of patients with NF-2 are at highest risk for multicentric intracranial neurilemmomas and meningiomas.^{99,101} Not all of the phenotypic heterogeneity, however, is explained by inherited differences in the pattern of *NF2* mutations because variable patterns of tumor growth have been noted among patients with identical mutations and even among identical twins.¹⁰² The latter observation has important implications for the screening of patients with NF-2. Presently, it is impossible to predict which patients will develop multiple intracranial tumors, and in the absence of a conclusive genotype–phenotype correlation, periodic cranial neuroimaging is advocated in all affected patients. Occasionally, patients with NF-2 will initially present with seizures from meningioangiomas, which is a hamartomatous proliferation of capillary-size vessels, meningothelial cells, and fibroblasts within the cerebral cortex. It may occur with or without concurrent meningioma formation.¹⁰³

From a therapeutic standpoint, many of the above comments regarding vestibular neurilemmomas apply to other intracranial neurilemmomas and meningiomas. These lesions exhibit unpredictable biological behavior; some tumors remain quiescent for extended intervals, whereas others enlarge rapidly, necessitating vigilant imaging and clinical follow-up. Because affected patients will often develop multiple intracranial neurilemmomas and meningiomas, we generally reserve operative intervention for those who have lesions that cause obvious neural compression or that exhibit progressive growth.

Intraparenchymal Gliomas

Patients with NF-2 may develop intrinsic glial neoplasms of the brain, but such lesions are less commonly seen than in patients with NF-1. In contrast, intraspinal intramedullary tumors are more common in patients with NF-2.^{21,82,104,105} In such patients, ependymomas are more frequent than astrocytomas, whereas the converse is observed in patients with NF-1.¹⁰⁶ Because ependymomas are generally well circumscribed, complete resection is often feasible and is indicated for lesions that are large and those that show definite signs of progression.^{21,106}

Extracranial Neurilemmomas and Meningiomas

A significant percentage of patients with NF-2 exhibit intraspinal growth of nerve sheath tumors and meningiomas (► Fig. 48.12).^{82,105} Because these tumors grow slowly and displace rather than invade the surrounding neural structures, impressively large lesions may be asymptomatic for years

Fig. 48.13 Magnetic resonance image of an 18-year-old male with multisegmental intraspinal tumors causing progressive myelopathy. Three discrete lesions of the cervical and thoracic regions were removed; two proved to be meningiomas and one was a neurilemmoma.

before cord compromise is clinically apparent. We generally favor tumor resection for patients with radiographic evidence of pronounced cord compression, even in the absence of symptoms. Because the nerve sheath tumors in NF-2 are usually neurilemmomas¹⁰⁷ rather than neurofibromas, extracranial lesions are generally well circumscribed and arise from a single nerve fascicle, which often can be sacrificed with minimal neurologic morbidity.⁷⁰ In general, meningiomas can be removed without

resecting any neural elements. A small percentage of patients have neurofibromas, which pose the same difficulties as those arising in the context of NF-1.⁸² In some instances, patients will require the removal of several lesions at different levels because of profound multisegmental cord compression (► Fig. 48.13).^{82,99,105} Our observation has been that children who exhibit intact neurologic function preoperatively maintain this during the postoperative period and many patients with deficits improve, whereas those with profound impairment usually fail to recover, which supports the concept of early surgery. However, we do not routinely remove lesions that are producing little or no spinal cord compression and, instead, follow these patients periodically with clinical evaluations and MR imaging examinations of the spine.

48.3 Counseling

Beyond the acute evaluation and management of specific medical and surgical problems that arise in patients with NF-1 and NF-2, there are issues related to having a genetic disorder, especially a chronic one affecting multiple systems, that are best addressed by a clinical geneticist or genetic counselor. This person clarifies inheritance risks in terms understandable to the patient or parents. The family may wish to learn about technical details regarding reproductive options to avoid having additional children with NF, including prenatal diagnosis, gene testing, and assisted reproductive procedures. Because gene testing is now commercially available, the pros and cons of undergoing DNA analysis of the genes for NF-1 and NF-2 need to be the subject of extended discussion. The geneticist also offers anticipatory guidance and conducts or expedites diagnostic examinations for other family members who, by their position in the family tree, may be at risk for NF.

Because patients and families affected by NF-1 and NF-2 are faced with a lifetime of uncertainty regarding the natural history of the disorder, which may be superimposed on chronic difficulties in learning and socialization (in NF-1) and cosmetic concerns (in both disorders), social services or psychological support is often beneficial. Finally, local support groups, often affiliated with one of the national organizations in the United States, such as the National Neurofibromatosis Foundation (<http://www.nf.org>), the Children's Tumor Foundation (<http://www.ctf.org>), and the Neurofibromatosis Network (<http://nfnetwork.org>), provide patients and families with an opportunity to share their experiences with others and keep abreast of new developments in the field. Finally, a geneticist, neurologist, or knowledgeable generalist, such as a family practitioner, pediatrician, or internist, should monitor the patient according to published guidelines for health supervision,²⁷ to complement the periodic comprehensive evaluations that are provided by a multidisciplinary NF clinic.

Pearls

- Because NF-1 and NF-2 are multisystem disorders, patients often present with symptoms and signs not directly referable to a central nervous system tumor. Recognition of the significance of these findings and knowledge of the indications for intervention are essential for optimizing outcome. The complexity of the diagnostic and management decisions that arise in children with NF-1 and NF-2 support the use of a multidisciplinary approach to patient management.
- By far the most commonly detected abnormalities on MR imaging in children with NF-1 are foci of increased signal on T2-weighted images without T1 signal change or mass effect. Because these lesions typically follow a benign course, their management must be conservative.
- The management of children with NF-1 and optic pathway tumors must be individualized because the natural history of these lesions varies widely.
- Although optic gliomas and intrinsic brainstem gliomas in children with NF-1 seem to differ biologically from similar-appearing lesions in patients without NF-1, cerebral and cerebellar hemispheric gliomas and exophytic brainstem gliomas in patients with NF-1 should be managed according to the same guidelines used for patients without NF-1.
- The majority of peripheral nerve tumors in patients with NF-1 are neurofibromas, whereas those in patients with NF-2 are neurilemmomas. Although isolated neurofibromas may be amenable to complete resection, plexiform lesions can rarely be completely removed without unacceptable morbidity. Neurilemmomas are usually amenable to complete resection.
- Because patients with NF-1 and NF-2 may have multiple central nervous system tumors, intervention is usually reserved for lesions that cause or are highly likely to cause, progressive neurologic dysfunction and for those that show relentless growth.

49 The Phakomatoses

Robert P. Naftel and Ian F. Pollack

The term *phakomatosis* was first coined by ophthalmologist Jan van der Hoeve in 1920 to compare similarities between neurofibromatosis and tuberous sclerosis.¹ In doing so, he defined the term *phakoma* to describe congenital tumors in multiple tissues distinct from nevi by the lack of nevus cells.² When he coined the term, strict inclusion or exclusion criteria for this category were omitted. Over time, because of this looseness of definition, many conditions have been included in the category. Another popular term for these conditions is *neurocutaneous disorders*.

The syndromes that are covered in this chapter are the more common phakomatoses, as well as the conditions that are the most relevant to neurosurgeons. They include tuberous sclerosis, Sturge-Weber syndrome, von Hippel-Lindau syndrome, hereditary hemorrhagic telangiectasia, basal cell nevus syndrome, and neurocutaneous melanosis. Neurofibromatosis is discussed in a separate chapter but is a member of this group. Other syndromes that could be included in this category are ataxia telangiectasia, incontinentia pigmenti, and Wyburn-Mason syndrome.

49.1 Tuberous Sclerosis Complex

49.1.1 Introduction

Tuberous sclerosis complex (TSC) is a genetic disorder with variable penetrance that causes multiple-organ dysfunction. Tumors can form in the brain, kidneys, heart, eyes, lungs, and skin. In 1862, the constellation of findings was first noted by von Reckinghausen.³ However, the disorder did not receive its name until Magloire Bourneville applied the term *sclérose tubéreuse* to describe the gross appearance of the autopsy findings.⁴ The disorder is relevant to neurosurgeons because 85% of children have neurologic sequelae, including epilepsy, tumors, and behavioral and psychological problems.⁵

49.1.2 Epidemiology

From 1 in 6,000 to 1 in 14,000 children younger than age 10 are estimated to have TSC,^{6,7} but the prevalence may be higher because of the variable severity of disease expression.⁸ When the difference in expression is accounted for, the birth incidence is estimated to be 1 in 5,800.⁹ There are no known demographic categories that are predominantly affected.

49.1.3 Clinical Presentation

The most common cutaneous finding is hypopigmented macules, also known as ash leaf spots, which are present in 90 to 98% of patients with TSC patients versus only 4.7% of the general population (► Fig. 49.1).^{5,10,11} These lesions are most easily detected with a Woods lamp and are often located on the trunk or buttocks.¹¹ Bilateral facial angiofibromas (also known as adenoma sebaceum), which form a butterfly pattern over the bridge of the nose and malar eminences, are present in 80% of

children with TSC who are older than 5 years (► Fig. 49.2).¹¹ Shagreen patches, present in 54% of patients older than 5 years, are connective tissue nevi found commonly on the lumbosacral flanks or dispersed over the trunk and thighs.¹² Forehead fibrous plaques are another type of angiofibroma found in about 36% and may be present at birth.¹² Periungual fibromas (also known as Koenen tumors), which usually do not develop until age 15 to 29, are more common in women and preferentially form on toes. Molluscum fibrosum pendulum (also known as a skin tag) is commonly found in adults and is located on the neck, groin, axillae, and flexor surfaces of limbs.¹¹ Dental pits are present in 90% of patients with TSC, whereas they are present in only 9% of the general population.¹³

Cardiac rhabdomyomas, an almost exclusively pediatric manifestation of TSC, are a primary finding in fetuses and infants. Of infants with cardiac rhabdomyomas, 96% are diagnosed with TSC.¹⁴ Generally, these lesions are asymptomatic and detected on fetal ultrasound or when a murmur is present. Occasionally, they can be large enough to cause cardiac output dysfunction or significant arrhythmias. These tumors regress throughout early childhood, with the most dramatic reduction occurring during the first 3 years of life.^{15,16}

Fig. 49.1 An 8-year-old boy with hypopigmented macules (also known as ash leaf spots). These lesions are most often located on the trunk or buttocks.

Fig. 49.2 An 11-year-old boy with bilateral facial angiofibromas (also known as adenoma sebaceum), which form a butterfly pattern over the bridge of his nose and malar eminences.

Kidney complications are the most common tuberous sclerosis-related cause of death.¹⁷ The renal manifestations include renal angiomyolipomas, renal cysts, and renal cell carcinoma (RCC). Although renal angiomyolipomas are predominantly present in adults, up to 16% of children younger than 2 years old can be affected and may require treatment, either through embolization or surgical resection.^{18,19} Renal cysts may be present but are usually asymptomatic. RCC is present in 2 to 3% of patients with TSC and is usually diagnosed during childhood.²⁰

Although extremely rare in pediatric TSC, pulmonary lymphangiomatosis is a progressive disease process that begins with shortness of breath, cough, and chest pain. It can be very difficult to treat.²¹

On ophthalmologic examination, retinal hamartomas are found in 40 to 50% of patients. These hamartomas have variable morphological appearances but rarely affect vision.²²

Neurologic sequelae of TSC include epilepsy, neoplasms, hydrocephalus, and neurocognitive or behavioral dysfunction. On magnetic resonance (MR) imaging, affected patients typically exhibit multiple characteristic structural abnormalities, including cortical tubers, which may or may not be calcified; subependymal nodules, which do not enhance; and subependymal giant cell astrocytomas (SEGAs), which are enhancing, noncalcified lesions near the foramen of Monro (► Fig. 49.3). These lesions contribute to the neurologic manifestations listed above.⁷ The tubers can be located anywhere in the cortex; however, they are most commonly located in the frontal and parietal lobes. They represent focal areas of cortical dysplasia and appear as expanded gyri with high intensity on all MR imaging sequences (► Fig. 49.4). Tubers do not generally enhance with contrast. Subependymal nodules have the appearance of periventricular “candle drippings” that do not enhance.²³

Epilepsy is associated with the cortical tubers; however, it is not clear whether the tubers themselves or the perituberal cortex is epileptogenic.^{24,25} The prevalence of epilepsy in TSC is reported to be 80 to 90%.⁹ In children who develop epilepsy, seizures typically begin in the first year of life, and 85% of cases will be refractory to medical treatment. Usually, the seizures are focal at first; however, they can be preceded by or progress

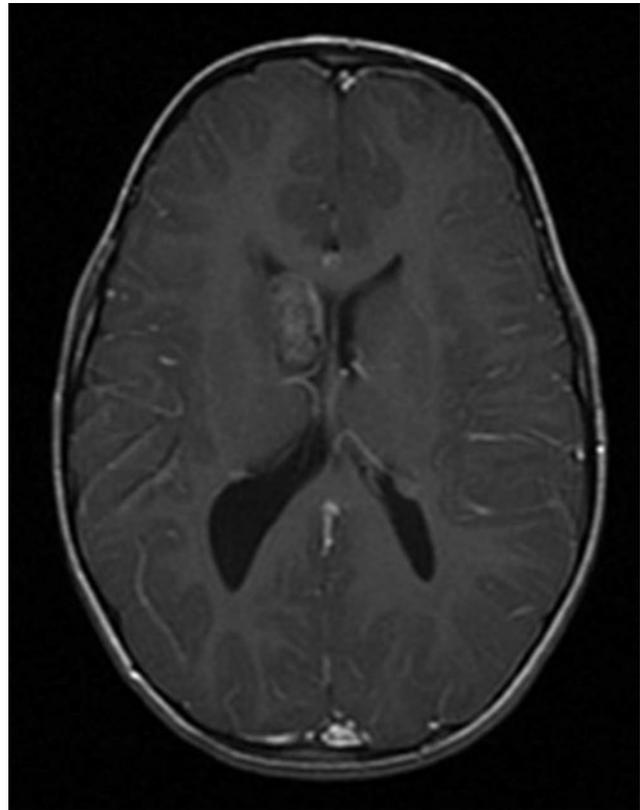

Fig. 49.3 Magnetic resonance imaging of the brain of a 4-year-old girl with tuberous sclerosis complex. This axial T1-with-contrast sequence demonstrates a subependymal giant cell astrocytoma, which is an enhancing, noncalcified lesion near the foramen of Monro.

to infantile spasms. Infantile spasms usually evolve into other types of seizures, oftentimes leaving children with multiple seizure types.²⁶ These children are at an increased risk for developing neurocognitive disabilities.²⁷ Generally, children with *TSC2* genetic mutations are at higher risk for developing more severe seizure phenotypes.²⁸

SEGAs are tumors near the midline in close proximity to the foramen of Monro that develop in 5 to 15% of patients with TSC.^{29,30} They most commonly occur in the first two decades of life; the mean age at presentation is 11 years.³¹ SEGAs grow slowly and are generally 2 to 3 cm at the time of diagnosis. As World Health Organization (WHO) grade I tumors, they generally cause symptoms from mass effect, either through hydrocephalus or direct compression of the deep nuclei.³² On imaging, they can be difficult to differentiate from subependymal nodules. However, if a lesion is larger than 12 mm, enhances, and is near the foramen of Monro, it is likely an SEGA.³³

Neurocognitive function varies from nearly normal to severely disabled, the latter often reflecting autistic or other neurobehavioral disorders. About 30% of children are extremely impaired, without the ability to live an independent life. However, 50% may have a normal IQ but still have some cognitive deficits.³⁴ There are high rates of autism associated with TSC.^{35,36} Poor cognitive outcomes have been linked to intractable seizures, *TSC2* mutation, and the location of cortical tubers.³⁷

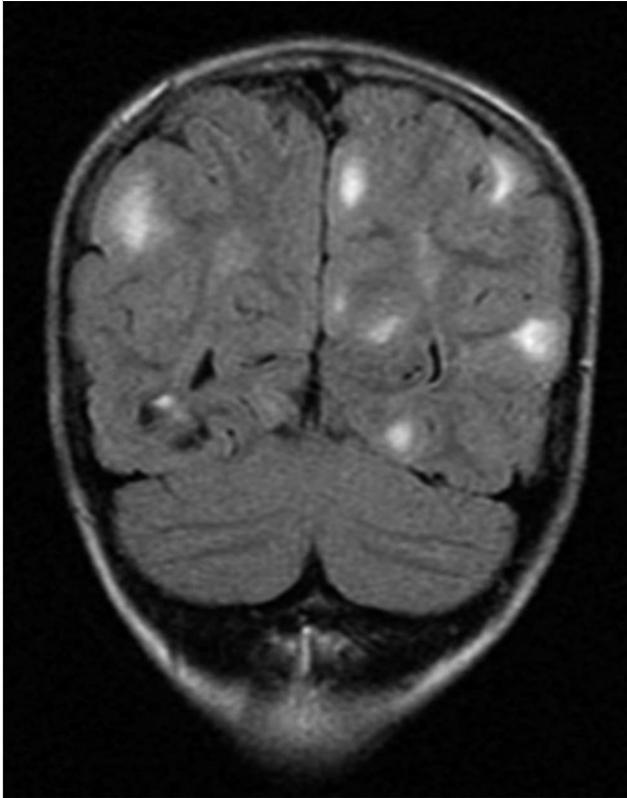

Fig. 49.4 Magnetic resonance (MR) imaging of the brain of a 4-year-old girl with tuberous sclerosis complex. This coronal fluid-attenuated inversion recovery (FLAIR) sequence demonstrates tubers, which represent focal areas of cortical dysplasia and appear as expanded gyri with high intensity on all MR imaging sequences. Tubers do not generally enhance with contrast.

49.1.4 Pathology and Genetics

TSC is an autosomal-dominant inherited disorder. However, nearly two-thirds of cases are believed to result from sporadic mutations.^{9,38} The mutations have been identified as affecting two tumor suppressor genes, tuberous sclerosis complex 1 (*TSC1*), and tuberous sclerosis complex 2 (*TSC2*), and have been mapped to chromosomes 9q34 and 16p13.3, respectively.^{39,40} Of the sporadic mutations, *TSC2* mutations are the most common, responsible for 75 to 80% of cases.⁴¹ *TSC1* and *TSC2* encode the proteins hamartin and tuberin, respectively. Under normal conditions, the proteins act as a dimer that activates a guanine triphosphatase (GTPase). This acts as a negative downstream regulator of the mammalian target of rapamycin (mTOR), which has been the therapeutic target of rapamycin and similar drugs.⁴² Dysregulated mTOR activation has been implicated in the development of SEGAs and of cortical dysgenesis.⁴³ Patients with the same genotype, even within a family, can exhibit very different phenotypes. Although there are exceptions, generally *TSC2* mutations have more severe clinical manifestations than *TSC1* mutations.^{41,44}

49.1.5 Diagnostic Studies

A consensus conference defined criteria for the diagnosis of TSC. These criteria include major and minor features, and the

diagnosis is made when a patient exhibits two major or one major and two minor features. The features include clinical signs and radiologic findings that are specific for tuberous sclerosis.⁴⁵ These diagnostic criteria do not include genetic testing. Genetic testing is informative if the results are positive; however, it detects only 85 to 90% of *TSC* mutations, which is considered a relatively low sensitivity.⁴⁶

When a child is diagnosed with TSC, many diagnostic studies are needed to assess the degree of systemic involvement (see box “Tuberous Sclerosis Management (p.644)”⁷). Throughout childhood, the patient undergoes surveillance monitoring to identify the frequent complications of TSC that are treatable if diagnosed early but are highly likely to cause morbidity or mortality if the diagnosis is delayed (see box “Tuberous Sclerosis Management (p.644)”⁷). Therefore, testing is directed toward diagnosing renal angiomyolipomas, SEGAs, cardiac rhabdomyomas, and pulmonary lymphangiomyolipomas, because these are the major causes of premature mortality in TSC.^{7,17} Any of these evaluations should be repeated more frequently when clinically indicated.⁷

Tuberous Sclerosis Management

- Initial evaluation
 - Magnetic resonance (MR) imaging of the brain with and without contrast
 - Electroencephalography (EEG; less essential in older children who are developmentally normal and without seizures at the time of diagnosis)
 - Neurodevelopmental testing
 - Electrocardiography to evaluate for arrhythmias
 - Echocardiography if there are arrhythmias or cardiac dysfunction
 - Renal ultrasound
 - Ophthalmologic examination
 - Dermatologic examination for concerning cutaneous manifestations
- Surveillance
 - MR imaging of the brain every 1 to 3 years
 - Renal ultrasound every 1 to 3 years
 - Neurodevelopmental testing repeated at school entry
 - Repeated electrocardiography, echocardiography, EEG, ophthalmologic evaluation, and dermatologic evaluation as clinically indicated

Data from Curatolo P, Bombardieri R, Jozwiak S. Tuberous sclerosis. *Lancet* 2008;372(9639):657–668.⁷

49.1.6 Treatment

A multidisciplinary approach is required to manage patients with TSC. The treatment of the nonneurosurgical features of TSC is beyond the scope of this chapter, but patients should undergo the previously described surveillance testing and be treated as needed by the appropriate medical specialists.⁷

Traditionally, surgery has been the treatment of choice for SEGAs, and it is curative with complete resection.³³ These tumors are usually resected through a transcallosal or transcortical approach; however, authors have described purely endoscopic

approaches.⁴⁷ When complete resection cannot be achieved, patients typically experience slow growth of the tumor residual that requires further treatment.⁴⁸ Gamma Knife has been used as both primary and adjuvant treatment; however, the results have not been consistently promising.^{49,50} Recent breakthroughs in pharmacologic therapy for SEGAs have taken advantage of mTOR pathway inhibition and have used rapamycin (sirolimus), its prodrug CCI-779 (temsirolimus), or its analogue RAD001 (everolimus) to counteract the uncontrolled mTOR pathway.³¹ These drugs are still currently being investigated, but it is notable that significant reduction in tumor size occurred in the majority of patients; however, the reduction was not durable after the cessation of treatment.⁵¹⁻⁵³ The exact role of mTOR inhibitors is still being established through ongoing clinical trials. It is likely that there are clinical scenarios that will be managed by using mTOR inhibitors as either neoadjuvant therapy or for residual or surgically inaccessible lesions.³¹

Despite the use of multiple antiepileptic drugs (AEDs), many children develop intractable epilepsy.²⁶ These patients are candidates for surgical evaluation for resection of the primary epilepsy focus or, in some cases, insertion of a vagal nerve stimulator. Another option is a ketogenic diet.⁵⁴ For the treatment of infantile spasms, vigabatrin is the first-line therapy, even though there can be significant ophthalmologic complications.⁵⁵ Second-line therapy includes corticosteroids or other AEDs. For infantile spasms, surgery can be an option if the infantile spasms are believed to be generated by a focal lesion.⁵⁶ For focal seizures, vigabatrin is recommended if the child is younger than 1 year; other AEDs are used if the patient is older than 1 year. Surgery should be considered early as a second-line therapy if the seizures are refractory to AEDs and the patient has a surgically resectable localized lesion.⁵⁶ Third-line therapy would be vagal nerve stimulation or a ketogenic diet.^{54,56,57}

Patients for whom surgery is being considered should proceed through the usual epilepsy surgical evaluation, which may differ slightly among centers but includes noninvasive video electroencephalography (EEG), MR imaging, positron emission tomography (PET), single photon emission computed tomography (SPECT), magnetoencephalography (MEG), and neurocognitive testing. In many cases, the evaluation leads to invasive monitoring with subdural and depth electrodes.⁵⁶ Sometimes, a multistage operation is required for a patient with multiple epileptogenic foci.⁵⁸

Despite these epilepsy treatment options, up to one-third of patients remain resistant to treatment. Current investigations are examining the role of mTOR inhibitors for epilepsy, in parallel with the use of these agents for the treatment of SEGAs.⁴³ In studies of mTOR inhibitors for the treatment of SEGAs, patients were noted to have a reduction in seizure frequency.⁵³ The potential of using mTOR inhibitors to treat epilepsy is offset by the probable need for long-term therapy and potential side effects or toxicity profile, as well as the complexity of enzyme upregulation that occurs with many AEDs.

49.1.7 Prognosis

Early death in patients with TSC is most often caused by complications of renal disease.¹⁷ Early death can also be due to status epilepticus or hydrocephalus secondary to SEGAs.³⁰

49.2 Sturge-Weber Syndrome

49.2.1 Introduction

Sturge-Weber syndrome (SWS), also known as encephalotrigeminal angiomas, is a sporadic congenital disorder affecting the brain, face, and eyes.⁵⁹ In 1879, William Sturge first described the clinical syndrome,⁶⁰ and in 1922, Frederick Weber described the radiographic findings as well as the pathophysiologic vascular steal phenomenon.⁶¹ Unlike most other phakomatoses, SWS is not inherited and is not associated with neoplasms; however, SWS is relevant to neurosurgeons because of the prevalence of intractable epilepsy and the potential need for epilepsy surgery.⁶²

The syndrome consists of multiple clinical and radiologic findings, including a facial port-wine stain (PWS), leptomeningeal angiomas, angiomas of the choroid plexus, and congenital glaucoma. Three variants of SWS have been described, spanning a spectrum of disease severity. Type 1 is the traditionally described SWS, with the facial PWS, leptomeningeal angiomas, choroid angioma, and congenital glaucoma. Type 2 is the PWS alone without intracranial involvement. Lastly, type 3 is exclusively leptomeningeal angiomas and occurs in about 10% of cases.^{63,64}

49.2.2 Epidemiology

The prevalence is estimated to be 1 in 50,000 live births. No gender or racial predilection exists.⁶⁵

49.2.3 Clinical Presentation

The clinical manifestations vary in severity among patients and can progress over time. Typically at birth, patients with SWS exhibit a PWS, which is a facial capillary malformation.⁵⁹ This facial stigma can have variable appearances, including that of a salmon patch; however, throughout this chapter, it is referred to as a PWS. Most often, a PWS is located in the V₁ distribution of the trigeminal nerve, but it can extend into the V₂ or less commonly the V₃ distribution.^{59,66,67} In up to 10% of patients, the PWS can be bilateral (► Fig. 49.5).⁶⁸

Leptomeningeal angiomas develops in only 8 to 20% of children born with a PWS. The presence of leptomeningeal angiomas is more likely when the PWS is in the V₁ distribution, large, or bilateral.⁶⁶⁻⁶⁸ If the PWS is unilateral, then any leptomeningeal angiomas is generally ipsilateral. The parietal and occipital lobes are the most common location for leptomeningeal angiomas, but it can cover an entire hemisphere or be bilateral.⁶⁹

Epilepsy, developmental delay, cognitive deficits, headaches, spastic hemiparesis, and cerebral ischemia with transient ischemic attacks and strokes can occur.⁷⁰⁻⁷³ Seizures occur in nearly 75% of patients with unilateral disease and in 95% of those with bilateral disease.^{69,71} They begin at a median age of 6 months; among 75% of patients with SWS in whom epilepsy develops, seizures begin in the first year of life.^{72,73} Intractable epilepsy is associated with seizures beginning in the first year of life, but much of the natural history of this condition is still unknown.⁷⁴ Initially, the seizure type is usually simple partial; however, some patients have complex partial seizures,⁷⁵ and the seizures

Fig. 49.5 An infant with a port-wine stain in a bilateral cranial nerve V₁ distribution. Bilaterality is uncommon but can be present in up to 10% of patients.

may cluster, alternating with periods of seizure freedom.^{10,75,76} Rarely, patients with SWS can have infantile spasms.^{77,78} In patients with isolated leptomeningeal involvement (type 3), the seizures usually begin later and are more easily controlled with AEDs.⁶³

“Strokelike episodes” can occur, with prolonged hemiparesis persisting days to months or even permanently; these episodes are of longer duration than the usual Todd paralysis.⁷⁵ Seizures, minor traumas, and migraine headaches have been reported as precipitating events.^{75,79,80} Progressively, patients can develop spastic hemiparesis and visual field deficits, but the frequency of these developments has not been reported.⁷⁵

Headaches are a common complaint in patients who have SWS, with a frequency much higher than that in the general population.^{81,82} Migraines can be temporally related to seizures and strokelike episodes.⁸⁰

Cognitively and psychologically, patients range from normal to severely disabled. More severe cognitive deficits have been associated with the early onset of seizures, intractable epilepsy, multiple seizure types, a greater degree of cerebral atrophy, and bilateral involvement.^{69,73,75} School-age children are more likely to be diagnosed with attention deficit disorders.

Glaucoma develops in 30 to 70% of patients. Of those in whom glaucoma develops, 60% present in infancy and 40% in childhood or early adulthood.⁷³ Glaucoma is the result of ocular capillary venous vascular malformations.⁶⁸

49.2.4 Pathology and Genetics

Although there is no genetic inheritance of SWS, somatic mosaicism may play a role.⁷⁵ Embryologically, the constellation of findings associated with SWS point to the sixth week of fetal development for the timing of the dysfunction. In normal development, a vascular plexus forms around the cephalic portion of

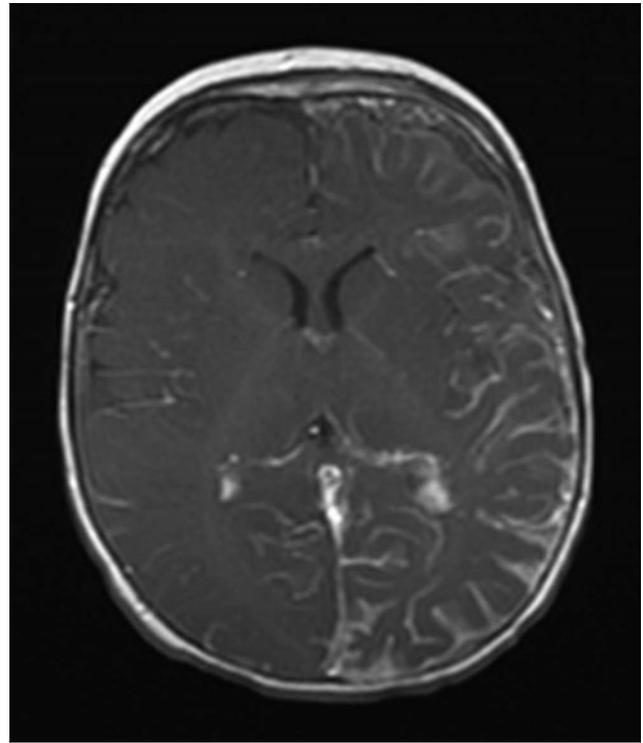

Fig. 49.6 Magnetic resonance (MR) imaging of the brain of an 11-month-old boy born with a left-sided port-wine stain in the distribution of cranial nerve V₁. Initial MR imaging at 7 months was normal. On this axial T1-with-contrast sequence, left hemispheric leptomeningeal angiomatosis is demonstrated.

the neural tube and in proximity to the ectoderm that will form the facial skin. Normally, this vascular plexus regresses during the ninth week of development. It is hypothesized that the vascular plexus fails to regress in SWS.^{65,83} Fibronectin expression may play a role in this process.^{3,84}

Pathologically, the normal vascular network of the brain is altered in SWS such that the cortical vessels are hypoplastic, the deep venous structures are usually dilated, and the leptomeningeal vessels are enlarged.⁵⁹ Microscopic examination reveals calcium in the cortex with gliosis and hypoplastic vessels.⁶⁵ Serial SPECT examinations demonstrate that blood supply to the affected cortex decreases progressively over the first year of life.⁸⁵ Also, during seizures, blood flow is significantly decreased in the surrounding brain, creating a vascular steal phenomenon.^{68,86} Therefore, seizures may exacerbate ischemia.⁸⁷

49.2.5 Diagnostic Studies

MR imaging is the radiologic test of choice for diagnosing leptomeningeal angiomatosis, which is visualized best on T1-weighted contrasted images (► Fig. 49.6). A choroid angioma with hypertrophy or dilation of the ipsilateral choroid plexus can be noted in older children. Newer MR imaging sequences, such as susceptibility-weighted imaging, are improving the diagnostic sensitivity of MR imaging by detecting the cortical calcification and dilated transmedullary and subependymal veins that may precede other MR imaging findings.^{88,89}

Additionally, MR imaging perfusion and diffusion abnormalities have correlated with clinical findings such as hemiparesis, seizures, and cognitive performance.^{90–92} Computed tomography (CT) is also useful for demonstrating gyriform cortical and choroidal calcifications, which are often absent in infancy. Because of the vascular steal phenomenon, the affected part of the brain atrophies and the calvaria secondarily thickens.^{93,94}

When patients present with strokelike episodes, they typically undergo CT (to rule out hemorrhage), EEG, and MR imaging. MR imaging may reveal diffusion abnormalities that are not in a large-vessel distribution. These are believed to be due to microvascular stasis.^{75,95}

In an infant with a PWS, leptomeningeal angiomatosis can be difficult to diagnose because neither CT nor MR imaging is sensitive in this age group.⁸⁸ Imaging may need to be repeated between the ages of 1 and 2 years to rule out intracranial involvement. Generally, it can be assumed that if a child older than 1 year with a PWS is developing normally, without seizures, and has normal findings on neurologic examination and contrasted brain MR imaging, then leptomeningeal involvement is unlikely.^{59,88}

Metabolic neuroimaging modalities, such as fluorodeoxyglucose F 18 PET, can assist in a comparison of glucose utilization in the affected and unaffected hemispheres and potentially in making decisions about the timing and technique of epilepsy surgery.^{75,96,97}

49.2.6 Treatment

A multidisciplinary approach is required for the care of SWS patients. They often require the care of a neurologist, ophthalmologist, dermatologist, and potentially a neurosurgeon. Because of the risk for glaucoma, even in infants, an ophthalmologist should be involved in the care of children with SWS.⁷⁵ Neurologists can treat migraines with the same strategies that are used for patients without SWS.^{75,98}

Neurologists can medically control seizures in 40% of cases.⁷⁰ When medical control cannot be obtained, surgery is considered. Because the neurocognitive and neurologic deficits can be progressive, determining the timing of surgery can be difficult. Surgeons differ on the optimal timing of the surgery. To prevent the adverse effects of continued seizures, some surgeons advocate early surgery.^{70,74,99} Others think it is better to be more selective because of the potential for gaining seizure control with AEDs and the possible complications of surgery.¹⁰⁰

Multiple surgical techniques have been employed, but hemispherectomy is the most effective in obtaining long-term control, and surgeons have reported good functional and quality-of-life outcomes.^{70,101} Hemispherectomy was first performed for this condition by Falconer and Rushworth.⁶² It is not clear whether there is an advantage of functional versus anatomical hemispherectomy in this patient population. Hemispherectomy is a reasonable choice for children with intractable epilepsy, hemiparesis, and visual field deficit. The more difficult decision pertains to the child with intractable epilepsy but without significant hemiparesis or visual field deficit.⁷⁵ Special considerations must be weighed regarding the child's vision. If a patient has normal visual fields, then the postoperative visual field deficit from a hemispherectomy

with the possibility of visual loss from glaucoma must be considered.⁵⁹ Although not as successful, more limited resections should be considered in patients without significant deficits. Surgery can be considered for patients with bilateral disease if monitoring localizes the seizures predominantly to one hemisphere.¹⁰²

The strokelike episodes are difficult to treat because their etiology is not completely understood, and the potential benefit of treating is debatable.⁷⁵ Because of the proposed etiology of microvascular stasis for this phenomenon, low-dose aspirin has been used with reports of decreased strokelike episodes and decreased seizures.^{103,104}

49.2.7 Prognosis

The prognosis depends on the severity of disease. There are no reasonable long-term studies reporting the lifetime prognosis for SWS patients. Neurocognitive and functional outcomes are the result of multiple factors, including seizures, AEDs, the vascular steal phenomenon, and cortical atrophy. Generally, patients who have better seizure control, either with AEDs or through surgery, have better outcomes.^{59,91}

49.3 von Hippel-Lindau Disease

49.3.1 Introduction

von Hippel-Lindau disease (VHL) is an autosomal-dominant genetic disorder that causes multiple neoplasms, including central nervous system (CNS) and retinal hemangioblastomas, pheochromocytomas, clear cell renal carcinoma, endolymphatic sac tumors, and pancreatic islet cell tumors. Renal and pancreatic cysts as well as epididymal and broad ligament cystadenomas can form.^{105,106}

In 1904, Eugene von Hippel, an ophthalmologist, described familial retinal angiomas,¹⁰⁷ later found to be histologically hemangioblastomas.¹⁰⁸ In 1926, Arvid Lindau, a pathologist, noted the association of these retinal hemangioblastomas and cerebellar hemangioblastomas.¹⁰⁹ There are now diagnostic criteria based on family history and clinical findings.¹⁰⁷

Although VHL-associated neoplasms develop relatively early compared with their sporadic counterparts, VHL remains primarily an adult disease.¹¹⁰ However, children can present with VHL.^{111,112}

49.3.2 Epidemiology

The incidence of VHL is 1 in 30,000 to 1 in 50,000 live births.^{113,114} It affects both sexes equally and can be found in all ethnic groups. There is a 90% penetrance by the age of 65.¹¹⁵ VHL accounts for a third of all CNS hemangioblastomas, more than half of retinal hemangioblastomas, and 1% of RCCs in the general population.¹¹⁶

49.3.3 Clinical Presentation

CNS hemangioblastoma is responsible for the presenting symptoms of 40% of patients at the time of VHL diagnosis.¹⁰⁵ These vascular tumors ultimately manifest in 60 to 80% of patients with VHL.^{105,117} Overall, VHL causes 5 to 30% of all cranial

hemangioblastomas and 80% of all spinal hemangioblastomas.¹¹⁸ The average age at a diagnosis of CNS hemangioblastoma is 29 years, although childhood cases are by no means rare.¹¹⁰ These tumors are most commonly located in the posterior fossa (75%), predominantly in the cerebellum but occasionally in the brainstem, and in the spinal cord (25%).^{119,120} The presenting symptoms are related to local mass effect, which can differ depending on whether the tumor is in the cerebellum, brainstem, or spinal cord. Because of this mass effect, posterior fossa hemangioblastomas often cause hydrocephalus. Additionally, the hemangioblastomas cause polycythemia in 5 to 20% of patients.¹¹⁸ Rarely, CNS hemangioblastomas are located in the supratentorial compartment.¹²¹

Retinal hemangioblastomas are the most common finding at presentation, and in half of cases, lesions are multiple or bilateral.¹²² By 50 years of age, the incidence of loss of vision is 35% in all *VHL* gene carriers and 55% in patients diagnosed with a retinal hemangioblastoma. Only 5% of cases are diagnosed before the age of 10 years.¹²³

Pheochromocytomas are important for neurosurgeons to identify because of their potential effect on operative conditions and postoperative care.¹²⁴ The incidence varies depending on the type of *VHL* (discussed below), but in most types the incidence ranges from 8 to 17%.¹⁰⁸ Pheochromocytomas can cause palpitations, unstable blood pressure, sweating, and headaches. Unlike most other *VHL* neoplasms, they are more likely to be detected in children and young adults than in older patients.¹²⁵

Endolymphatic sac tumors are present in 11% of patients and are usually asymptomatic at the time of diagnosis. When they do cause symptoms, hearing loss is usually the chief complaint, but they can also cause tinnitus and vertigo. With a mean age at diagnosis of 22 years, they can affect children.¹²⁶

The kidneys are affected with both clear cell renal carcinoma and renal cysts, but neither usually causes the initial presenting symptoms of *VHL*.^{118,127} Although the incidence of RCC varies depending on the type of *VHL*, in the most common types, the lifetime risk is about 70%.¹¹⁰ *VHL* is the most common cause of hereditary kidney cancer.¹⁰⁸ The average age at presentation is 40 years¹²⁸ however, asymptomatic lesions are frequently diagnosed earlier, but rarely before the age of 16 years.¹²⁹

Islet cell tumors and cysts affect the pancreas. Usually, the islet cell tumors are nonsecreting, and the cysts do not normally affect function.¹³⁰

49.3.4 Pathology and Genetics

Inheritance is autosomal-dominant, with about 20% of cases sporadic.¹¹⁸ The *VHL* tumor suppressor gene was mapped to chromosome 3p25.¹³¹ Many gene mutations have been discovered, creating a complicated genotype–phenotype relationship.¹³² Certain genotypes are more likely to be associated with specific tumors, such as pheochromocytomas, which has led to the definition of different “types” of *VHL*.^{116,133} The mutations can be missense, nonsense, or deletions.^{134,135} Prenatal testing is available.¹³⁶

Histologically, CNS and retinal hemangioblastomas are identical. These tumors are benign and highly vascular, consisting of large, lipid-laden stromal cells supported by a well-developed capillary network with many mast cells. The stromal cells show hyperchromasia and atypia, but almost no mitoses. The cyst fluid has a high concentration of erythropoietin.^{108,137}

49.3.5 Diagnostic Studies

In 1964, clinical diagnostic criteria were first proposed by Melmon and Rosen after review of the literature.¹⁰⁷ In a patient with a positive family history, the diagnosis is made if a single *VHL*-associated tumor is discovered. In the 20% of patients with sporadic *VHL*, either two or more CNS or retinal hemangioblastomas or a single hemangioblastoma and one other *VHL*-associated neoplasm must be present.^{107,134}

On CT and MR imaging, CNS hemangioblastomas have characteristic findings, which include a cystic component and an enhancing mural nodule (► Fig. 49.7). Spinal cord hemangioblastomas have an enhancing intramedullary component, often with a cystic component and associated syrinx. CNS hemangioblastomas often have large feeding and draining vessels.¹³⁸ The differential diagnosis can include juvenile pilocytic astrocytoma, ependymoma, and arteriovenous malformation.^{118,120,139}

Endolymphatic sac tumors are best diagnosed on MR imaging of the brain with and without contrast to evaluate for an enhancing mass, and on thin-cut CT through the temporal bone to evaluate for bone erosion associated with these tumors. Sometimes, these tumors can be occult on imaging.^{140,141}

CT and MR imaging of the abdomen can assist with the diagnosis of pheochromocytoma; however, laboratory tests are the gold standard. The diagnosis can be made with the measurement of either plasma fractionated metanephrines in high-risk patients or 24-hour urine fractionated or total metanephrines and catecholamines in lower-risk patients.¹⁴²

Screening recommendations have been proposed by Maher et al.¹¹⁶ Patients with *VHL* should undergo screening MR imaging of the brain and possibly spine every 1 to 3 years beginning

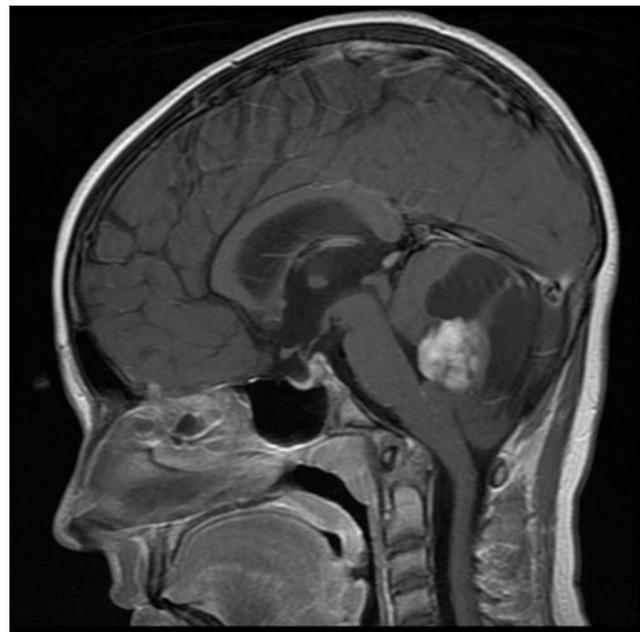

Fig. 49.7 Magnetic resonance imaging of the brain of a 10-year-old with von Hippel-Lindau disease. On this sagittal T1-with-contrast sequence, a posterior fossa hemangioblastoma is present, with the characteristic cystic component and enhancing mural nodule.

in adolescence. An ophthalmologist should screen for retinal hemangioblastomas annually beginning in infancy or childhood. Annual renal and pancreatic screening MR imaging or ultrasound should begin at the age of 16 years. For pheochromocytoma, blood pressure monitoring and 24-hour urine catecholamine metabolite studies should be performed annually beginning in childhood. In families at higher risk for pheochromocytoma, more intense surveillance, including annual plasma normetanephrine level measurement and adrenal imaging beginning at the age of 8 years, should be considered.

49.3.6 Treatment

Natural history studies of CNS hemangioblastomas describe saltatory growth patterns with intermittent, unpredictable periods of quiescence and growth.^{112,117,143} Not all tumors cause symptoms. In VHL, it is recommended that tumors be treated only when they are causing symptoms.^{112,141,143,144} Symptomatic tumors almost universally are associated with either cysts or peritumoral edema.¹⁴⁴ At this time, there is no way to predict which tumors will progress to cause symptoms and require surgical treatment.

Angiography can be useful for defining the vascular anatomy. Preoperative embolization has been used; however, it is often not possible because much of the blood supply may be provided by multiple small vessels that cannot be embolized.¹⁴¹ Also, there have been reports of significant morbidity and mortality associated with embolization of these tumors.^{145,146}

Surgical resection of symptomatic CNS hemangioblastomas is the recommended therapy. Because of the vascularity, careful microsurgical technique must be employed. Extracapsular dissection with careful coagulation and transection of tumor vessels is recommended.^{144,147,148} Disruption of the tumor capsule can cause troublesome bleeding. When there is an associated cyst, the cyst capsule is maintained as long as possible to assist with dissection. The cyst wall does not require resection because it is only compressed gliotic tissue.¹⁴⁹

A similar approach should be taken with spinal cord hemangioblastomas. In symptomatic lesions, surgical resection should be undertaken. Poor outcomes have been associated with a ventral location and not presenting to the pial surface.¹⁵⁰

Other treatment strategies include stereotactic radiation, with reports of short-term tumor control over 90%.¹⁵¹ However, at 15 years of follow-up, tumor control decreases to 51%.¹⁵²

In patients requiring surgical treatment of a CNS hemangioblastoma who also harbor a pheochromocytoma, alpha- and beta-adrenergic blockade must be employed preoperatively to safely manage the blood pressure perioperatively.¹⁵³

The treatment of other tumors associated with VHL is beyond the scope of this chapter.

49.3.7 Prognosis

The early diagnosis of retinal hemangioblastomas and RCCs has improved patient outcomes.¹¹⁰ The most common causes of death are RCC and complications of CNS hemangioblastomas. The median life expectancy is 49 years.^{118,154} Because of the availability of genetic testing and the potential for early diagnosis in familial cases, life expectancy may potentially be extended with early diagnosis and treatment.¹³⁶

49.4 Hereditary Hemorrhagic Telangiectasia

49.4.1 Introduction

Hereditary hemorrhagic telangiectasia (HHT), also known as Osler-Weber-Rendu syndrome, is one of the most prevalent autosomal-dominant conditions; there are only rare sporadic cases. The incidence is estimated to be 1 in 5,000 live births.¹⁵⁵ Genetic testing is available and is positive in 85% of cases.¹⁵⁶ The genetic mutations causing HHT have been linked to chromosomes 9q,¹⁵⁷ 12q,¹⁵⁸ 5q,¹⁵⁹ 18q, and 7p.¹⁶⁰

The syndrome is characterized by visible cutaneous telangiectases, mucosal telangiectases causing recurrent epistaxis and gastrointestinal bleeding, and the potential for multiple-organ arteriovenous malformations (AVMs).¹⁶¹ Telangiectases are usually located on the lips, tongue, face, fingers, and mucosa. They are pink to red pinhead-size lesions, or sometimes elevated, purple lesions. They can be differentiated from petechiae because they blanch with pressure and then immediately refill.¹⁶² The cutaneous stigmata of HHT are not present at birth but evolve and progress with age.¹⁶³ AVMs can form in the brain, spine, lungs, and liver. These patients also have higher incidences of anemia and thromboemboli due to elevated factor VIII levels, which occur in nearly 7% of patients.¹⁶⁴ The average age at the onset of epistaxis is 12 years.¹⁶³ Penetrance is age-related, approaching 100% by age 40.¹⁵⁵

The diagnosis is made with the Curaçao criteria, which include the presence of epistaxis, telangiectases, visceral lesions, and family history. Patients are given the diagnosis of unlikely, possible, or definite HHT depending on the number of clinical criteria that are met.¹⁶⁵ Genetic testing can be used to define the specific mutation in a family and then test other members of the family who may not meet the diagnostic criteria. Prenatal genetic testing can be performed for affected families. However, the benefit of such diagnosis has not been defined.¹⁶⁶

Although there is no definitive life expectancy study, a number of reports indicate that life expectancy is likely lower for all patients with HHT because of the risks for death early in life from cerebral AVMs^{167,168} and for pregnancy-related maternal deaths; there is a 1% risk for maternal or fetal death with pregnancy.¹⁶⁹ Five different types of HHT have been identified, and each is associated with different risk for certain AVMs.¹⁷⁰

49.4.2 Neurosurgical Implications

Up to 23% of patients with HHT also have some type of cerebral vascular malformation. Most commonly, these lesions are AVMs, arteriovenous fistulas, cavernous malformations, and telangiectases.¹⁷¹ Current HHT guidelines recommend that children and adults with possible or definite HHT (by the Curaçao criteria) be screened with MR imaging. Patients with an AVM diagnosed on MR imaging should be referred for more specific testing and treatment.¹⁶⁶ If a person's childhood screening MR imaging study is negative for a vascular malformation, there is insufficient evidence to recommend regular follow-up screening with MR imaging; however, consideration should be given to another single screening MR imaging study at the beginning of adulthood.¹⁶⁶ AVMs should be treated by neurosurgeons using the same clinical approach that they would use for sporadic

AVMs, including the possibilities of microsurgery, stereotactic radiation, and embolization.^{172–174}

Pulmonary AVMs occur in 15 to 50% of patients, and in addition to respiratory complications, there are multiple potential neurologic sequelae.^{175–177} Because of paradoxical embolism with right-to-left cardiovascular shunt, patients are at risk for transient ischemic attacks, ischemic strokes, and cerebral abscesses.¹⁷⁷ In fact, neurologic symptoms in HHT are more likely to be due to an ischemic stroke than to a hemorrhage from a cerebral AVM.^{167,177}

Fewer than 1% of patients develop spinal AVMs, which may present with paraparesis, paraplegia, myelopathy, or pain.^{18,19} No specific screening recommendations for spinal AVMs exist, but if an AVM is suspected, then MR imaging can be performed.¹⁶⁶ Treatment depends on the type of spinal AVM but can include embolization or microsurgery.¹⁷⁸

49.5 Basal Cell Nevus Syndrome

49.5.1 Introduction

Basal cell nevus syndrome (BCNS) is also known as Gorlin syndrome, Gorlin-Goltz syndrome, nevoid basal cell carcinoma, and basal cell carcinoma nevus syndrome. It has autosomal-dominant inheritance and is associated with the formation of basal cell carcinomas, odontogenic keratocysts, and skeletal anomalies. It was first defined as a syndrome in 1960 by Drs. Gorlin and Goltz.¹⁷⁹ The association between BCNS and medulloblastoma was first described by Herzberg and Wiskemann in 1963.¹⁸⁰ BCNS occurs in about 1 in 57,000 live births.¹⁸¹ The genetic mutations have been identified in the sonic hedgehog pathway.^{182,183} According to a consensus statement,¹⁸⁴ a diagnosis of BCNS can be reasonably considered if any of the following criteria are met: one major criterion and molecular confirmation, two major criteria, or one major and two minor criteria (see box “Diagnostic Criteria for Basal Cell Nevus Syndrome (p.650)”).

Diagnostic Criteria for Basal Cell Nevus Syndrome

- Major criteria
 - Basal cell carcinomas or number out of proportion to prior sun exposure and skin type before the age of 20 years
 - Odontogenic keratocyst of the jaw before the age of 20 years
 - Palmar or plantar pitting
 - Lamellar calcification of the falx cerebri
 - Medulloblastoma, typically desmoplastic
 - First-degree relative with basal cell nevus syndrome
- Minor criteria
 - Rib anomalies
 - Other skeletal malformations
 - Macrocephaly
 - Cleft lip/palate
 - Ovarian/cardiac fibroma
 - Lymphomesenteric cysts
 - Ocular abnormalities

Data from Bree AF, Shah MR. Consensus statement from the first international colloquium on basal cell nevus syndrome (BCNS). *Am J Med Genet A* 2011;155A(9):2091–2097.¹⁸⁴

Genetic testing is not required for diagnosis, and its sensitivity can be low.^{184,185} However, it can be helpful in selected cases, such as patients undergoing prenatal screening and patients who do not meet the clinical diagnostic criteria. In these cases, genetic confirmation could guide future screening tests to improve outcomes or the management of affected family members who do not yet meet the clinical criteria.¹⁸⁴

It is recommended that children diagnosed with BCNS undergo yearly evaluations by a geneticist to ensure that all multidisciplinary needs are being addressed. These patients require serial examinations and tests for the early detection of associated tumors and conditions.¹⁸⁴

49.5.2 Neurosurgical Implications

It is recommended that children up to the age of 8 years undergo annual brain MR imaging with and without contrast to evaluate for medulloblastoma.¹⁸⁴ When associated with BCNS, medulloblastoma is usually diagnosed in the first 2 years of life.¹⁸⁶ Medulloblastomas occur in 5% of patients with BCNS¹⁸⁷ in a male-to-female ratio of 3:1.¹⁸⁸ Often, the medulloblastoma can be the initial finding of BCNS, so careful evaluation for other diagnostic criteria should ensue.¹⁸⁹ Histologically, the medulloblastomas that form are desmoplastic and genetically linked to a loss of heterozygosity on chromosome 9q.¹⁹⁰ The prognosis of treated medulloblastomas associated with BCNS is better than that for sporadic medulloblastomas.^{186,190,191} Treatment includes aggressive resection, chemotherapy, and sometimes radiotherapy, although the administration of radiotherapy is somewhat controversial because of the high risk for radiation-induced basal cell carcinoma in this syndrome as well as other radiation-related tumors, such as sarcomas.^{186,192–194}

For spinal evaluation, it is recommended that these children undergo a first X-ray evaluation for scoliosis at the age of 1 year. If the result is abnormal, then the evaluation should be repeated every 6 months. If the result is normal, then the evaluation should be repeated if the child becomes symptomatic.¹⁸⁴ Spina bifida occulta, bifid vertebrae, and fused vertebrae are all associated with this syndrome.^{189,195}

These patients can also have macrocephaly,^{189,196} with abnormal head shapes and hypertelorism.¹⁹⁷ In 50% of patients, the head circumference is above the 95th percentile.^{189,196}

49.6 Neurocutaneous Melanosis

49.6.1 Introduction

First described in 1861 by von Rokitansky¹⁹⁸ and named in 1948 by Van Bogaert,¹⁹⁹ neurocutaneous melanosis (NCM) is a rare, sporadic, nonheritable disorder characterized by large congenital cutaneous melanocytic nevi and benign or malignant leptomeningeal melanosis. Hypothetically, it develops from a disorder in embryonic neuroectodermal morphogenesis resulting in the abnormal proliferation of melanin-producing cells.^{200–202}

NCM is equally prevalent in men and women,²⁰³ and the age at presentation is bimodal. Most frequently, NCM presents in the first 2 years of life²⁰¹; however, in a minority of patients, it presents the second and third decades of life.^{203,204} NCM can be

Fig. 49.8 A 2.5-year-old boy exhibiting multiple melanotic nevi associated with neurocutaneous melanosis.

Fig. 49.9 Magnetic resonance imaging of the cervical spine of an 18-month-old boy with neurocutaneous melanosis. On this sagittal T1-with-contrast sequence, leptomenigeal enhancement is demonstrated.

associated with other neurocutaneous disorders, such as neurofibromatosis type 1 and Sturge-Weber syndrome.²⁰⁵

Children with large cutaneous melanocytic nevi have a 1 to 12% chance of developing NCM.^{206–208} In two-thirds of patients, there is a giant nevus, usually located over the lumbosacral spine; in the remaining one-third, there are multiple smaller nevi (► Fig. 49.8).^{203,204} Malignant degeneration of leptomenigeal melanosis occurs in 40 to 60% of cases, leading to leptomenigeal melanoma.²⁰¹ Additionally, malignant transformation of the skin lesions can occur in 5 to 15% of patients; therefore, some dermatologists recommend prophylactic resection of some of these lesions.^{209,210}

The diagnostic criteria include the following: the presence of large or multiple congenital nevi (>20 cm in adults, ≥9 cm on the head or ≥6 cm on the body in infants); no evidence of cutaneous malignant change, except in patients with benign meningeal lesions; and no evidence of meningeal melanoma, except in patients with histologically benign skin lesions.²⁰¹

Definitive diagnosis requires histologic confirmation, which is often made only at autopsy; otherwise, the diagnosis remains provisional.^{200,201} Cerebrospinal fluid (CSF) sensitivity is only about 40%.^{201,211} Fortunately, MR imaging of the brain and spine is sensitive for detecting melanin in the leptomeninges.²¹² MR imaging is the diagnostic evaluation of choice for NCM. On MR images, the leptomenigeal melanosis appears hyperintense on T1 sequences and hypointense on T2 sequences because of the paramagnetic properties of melanin.^{213–215} Upon contrast administration, diffuse leptomenigeal enhancement of the brain and spine is often described (► Fig. 49.9).^{215,216}

49.6.2 Neurosurgical Implications

Hydrocephalus develops in about 60% of cases and often causes the presenting symptoms of the leptomenigeal process.^{209,217,}

²¹⁸ In NCM, hydrocephalus develops through multiple mechanisms: leptomenigeal infiltration by melanin causing direct obstruction to flow, decreased CSF resorption at the site of the arachnoid villi, or a Dandy-Walker complex.^{209,219} About 10% of patients with NCM have a Dandy-Walker complex.²²⁰ The developmental mechanism of the Dandy-Walker complex is hypothesized to be melanocyte infiltration of the cerebellum causing abnormal development and fourth ventricular outlet obstruction.^{201,221} The melanocytes can also invade the parenchyma, commonly the anterior temporal lobe and amygdala, causing seizures.²⁰⁵ NCM can cause many symptoms and signs²¹⁹ developmental delay²²² epilepsy, which can be intractable²²³ quadra- or paraplegia^{213,222} chronic psychosis²²⁴ and movement disorders.²²⁵ The spine is involved in about 20% of cases.²⁰⁵

Treatment includes ventriculoperitoneal shunting for the alleviation of hydrocephalus. Because there is rarely a focal lesion, such as a CNS melanoma, to be removed, resective surgery is generally not an option. Radiation and chemotherapy have not been found to be effective.^{226–228}

The prognosis is poor. Once they become symptomatic from the leptomenigeal process, half of patients die within 3 years,²⁰¹ and this appears to be independent of whether histologically they have a melanoma or benign melanosis.^{219,} ²²⁷ Patients with an associated Dandy-Walker complex have a poorer prognosis, usually dying before the age of 4 years.²²¹

Pearls

1. The management of each syndrome requires a multidisciplinary approach, and after diagnosis, many patients require regular surveillance screening tests.
2. Genetic testing is available for most of these conditions. However, diagnoses are made with criteria that do not include the results of genetic testing.
3. In TSC, the mTOR pathway inhibitors are promising treatments, with the potential to change treatment paradigms in SEGAs and epilepsy.
4. Patients with TSC and SWS are often candidates for epilepsy surgery.
5. Patients with TSC, VHL, or BCNS often develop CNS tumors requiring neurosurgical intervention.

50 Chemotherapy and Biologic Therapy for Pediatric Brain Tumors

Roger J. Packer and Tobey J. MacDonald

The current management of primary central nervous system (CNS) tumors of childhood has resulted in slowly improving survival rates and has become increasingly complex. Until the late 1970s and early 1980s, treatment for children with both benign and malignant brain tumors primarily consisted of surgery with or without radiation therapy. Chemotherapy was restricted to children with recurrent malignant brain tumors, usually with the goal of transiently prolonging life. A series of clinical investigations completed over the past quarter century has demonstrated the efficacy of chemotherapy for children with recurrent and newly diagnosed malignant and benign primary CNS tumors. For some brain tumors, such as medulloblastomas and possibly high-grade gliomas, chemotherapy at the time of diagnosis, when added to radiation therapy, improves the likelihood of survival.¹⁻³ Furthermore, for some children with nondisseminated disease, chemotherapy may allow a reduction in the dose of radiotherapy needed.⁴ In infants and very young children, chemotherapy is being increasingly used to delay, if not obviate, the need for alternative treatments.⁵ To date, the chemotherapies used to treat brain tumors have been primarily conventional cytotoxic agents, which relatively nonselectively kill tumor cells. However, recently, a host of biological agents have become available that are designed to target tumor cells and are in clinical trials.^{6,7} The specific role of this or any other type of chemotherapy in the management of childhood brain tumors is still being defined.

50.1 General Considerations

Discussions of the role of chemotherapy for childhood brain tumors have to take into account many factors. Childhood primary tumors of the CNS comprise a heterogeneous group of lesions. Generalizations are difficult to make, given the histologic and biological heterogeneity of these lesions.^{8,9} Even within recognized groupings—for example, medulloblastomas—there are now well-accepted molecular subgroupings, with likely different sensitivities to treatment and different prognoses.¹⁰ Obviously, for a chemotherapeutic agent to be effective, the tumor must be sensitive to the agent employed. The selection of a drug or drug regimen that is most likely to be effective for a given type of tumor has been primarily based on clinical studies investigating the response of the tumor to treatment.¹¹ Laboratory methods have been established to facilitate analysis of the biology and the therapeutic profile of a given tumor. Such laboratory approaches result in a more rational choice of chemotherapeutic agents to be evaluated. Agents with possible activity are tested by *in vitro* methods, and selected agents are further studied in animal models, such as a xenograft model in which human tumors are grown in immunodeficient (nude) mice. This rigorous means of testing allows potentially active new compounds to be identified before clinical trials are

undertaken. For biological agents, which may affect not only specific targets, such preclinical testing is likely even more important. Yet other factors, such as the ability of an agent to reach a tumor in effective concentrations, remain crucial.

50.2 Types of Drug Trials

The majority of drugs presently in use were chosen on the basis of their efficacy against other forms of cancer and subsequent results in clinical trials in adults and children with brain tumors (► Table 50.1). In general, these clinical trials can be separated into three major categories (► Table 50.2). Phase I trials are the initial trials, and the purpose of such studies is to determine the maximum tolerated dose of the drug, to identify its toxicities, and often to perform detailed pharmacokinetic studies. These studies are carried out in children with recurrent disease in whom all proven means of therapy have been exhausted. In pediatrics, the majority of drugs used for patients with brain tumors in Phase I testing have already been demonstrated to be somewhat efficacious in adults with primary CNS tumors. Many of the active antitumor agents now in use for patients with newly diagnosed brain tumors initially were tested in these Phase I clinical trial settings.

Once the optimal dose and schedule of a drug have been defined in a Phase I study, a Phase II trial is undertaken to determine the response rate of a specific tumor to the drug. The predominant measure of the efficacy of a drug in such trials is the objective response of the tumor to treatment, with a more than 50% reduction in tumor size on neuroradiographic studies considered a partial response and a complete disappearance of tumor considered a complete response. However, time to progression may also be used as a measure of effectiveness. Phase II trials are predominantly undertaken in children with recurrent disease. However, for some tumor types, especially those that are highly resistant to any known form of treatment, preradiation chemotherapeutic Phase II trials (which have also been titled *neoadjuvant trials*) have been performed. Reasons for using preradiation chemotherapeutic trials include that patients may be better able to tolerate a drug or drugs before other forms of therapy (primarily radiation therapy) have been delivered and that prior therapy may make a tumor more resistant to the effects of chemotherapy, thus causing active agents to be incorrectly considered ineffective.

The final step in the evaluation of the efficacy of a chemotherapeutic agent or a group of drugs is a randomized comparison of the efficacy of the drug or regimen, either in addition to conventional therapy or instead of conventional therapy, versus that of standard therapy. Given the relative rarity of pediatric CNS tumors, Phase III studies usually must be undertaken in a multi-institutional setting.

Table 50.1 Most common chemotherapeutic agents used for childhood brain tumors

Drug	Route	Tumor type	More common toxicities
Alkylating agents			
Cyclophosphamide	IV	Medulloblastoma Germ cell tumors	Myelosuppression Hemorrhagic cystitis
Ifosfamide	IV	Medulloblastoma	Hemorrhagic cystitis Reproductive
Melphalan	IV (ABMR)	? Medulloblastoma ? High-grade glioma	Myelosuppression Gastrointestinal
Thiotepa	IV (ABMR)	? Medulloblastoma ? High-grade glioma	Myelosuppression
CCNU (BCNU)	PO (IV)	Medulloblastoma High-grade glioma Oligodendroglioma	Myelosuppression Gastrointestinal Pulmonary
Cisplatin	IV	Medulloblastoma ? Ependymoma Germ cell tumors	Ototoxicity Nephrotoxicity Myelosuppression Peripheral neuropathy Nausea and vomiting
Carboplatin	IV	Low-grade glioma Medulloblastoma ? Ependymoma Germ cell tumors	Peripheral neuropathy Nausea and vomiting Myelosuppression
Procarbazine	PO	? High-grade glioma ? Low-grade glioma ? Oligodendroglioma	Myelosuppression Nausea and vomiting
Temozolomide	PO	? High-grade glioma ? Low-grade glioma ? Other	Myelosuppression Hepatotoxicity
Antimetabolites			
Methotrexate	PO, IV, ? IT	? Medulloblastoma ? High-grade glioma	Myelosuppression Gastrointestinal Hepatotoxicity
Cytosine arabinoside	IV, ? IT (? ABMR)	? Medulloblastoma	Gastrointestinal Hepatic
Plant alkaloids			
Vincristine	IV	Medulloblastoma Low-grade glioma ? High-grade glioma	Peripheral and autonomic neuropathy
Etoposide (VP-16)	IV or PO	? Medulloblastoma ? High-grade glioma ? Low-grade glioma Germ cell tumors	Myelosuppression

Abbreviations: ABMR, autologous bone marrow rescue; BCNU, bischloroethyl-nitrosourea; CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea; IT, intrathecal; IV, intravenous; PO, orally.

50.3 Determinants of Drug Efficacy and Drug Resistance

The efficacy of a chemotherapeutic agent is not dependent solely on the sensitivity of a tumor to the drug. Other factors are also of importance, including the following: pharmacokinetics of the drug, host pharmacogenomics, concurrent use of medications that may alter drug metabolism through the cytochrome P-450

system of the liver, ability of the chemotherapeutic agent to reach the tumor site in high enough concentrations to affect tumor growth, ability of the tumor cells to accumulate and retain the drug, and ability of the tumor cells to repair drug-induced damage.^{12–14} A great deal of emphasis has been placed on the delivery of the drug, or drugs, to the tumor, but increasing information suggests that equally important factors may be the cellular mechanisms within the tumor responsible for drug resistance.

Table 50.2 Investigational trials

Type	Goal	Patient population
Phase I	Determine maximum tolerated dose; ? dose searching	Recurrent tumors without known effective treatments; 15 to 30 patients
Phase II	Determine spectrum of agent; estimate disease-specific response rate	Recurrent tumors; newly diagnosed refractory tumors; 15 to 30 patients per tumor type
Phase III	Determine if more effective than currently available therapy	Usually newly diagnosed; often randomized

The blood–brain barrier has been identified as a major reason for the ineffectiveness of certain chemotherapeutic agents.^{15–17} In some pediatric brain tumors, such as medulloblastomas, which often have an abundant blood supply, the significance of the blood–brain barrier is unclear. For infiltrating gliomas, it is well documented that drug delivery is a more important issue because it is often difficult to deliver adequate concentrations of drugs to the periphery of the tumor.^{15–17} A variety of means have been used in attempts to improve drug delivery, including higher doses of chemotherapeutic agents, osmotic agents to disrupt the barrier, and more recently chemotherapeutic agents coupled with other drugs that selectively disrupt the tumor blood–brain barrier.^{15–19} For example, the anti-angiogenesis drug cilengitide, which targets integrins on ne endothelium, was found to improve the outcome of adult patients with glioblastoma multiforme (GBM) when it was administered with temozolomide chemotherapy; however, improvement was demonstrated only in those patients with tumors exhibiting MGMT (O6-methylguanine DNA-methyltransferase) promoter methylation, which confers sensitivity to temozolomide. This finding suggests that in this setting cilengitide was helping to increase the effective concentration of temozolomide delivered to temozolomide-sensitive tumors through its effect on normalization of the tumor vasculature.²⁰

The goal of high-dose chemotherapy is to increase the delivery of cytotoxic agents to tumor effectively by overcoming the limited permeability of the blood–brain barrier. Predominantly lipid-soluble alkylating agents with nonoverlapping hematologic toxicities have been chosen. Initially, trials were performed with one cycle of chemotherapy supported by autologous bone marrow transplant, but this type of support has been primarily supplanted by peripheral blood stem cell support. Toxicity with autologous bone marrow transplant protocols has been significant; in early trials, it was associated with a 5 to 15% treatment-related mortality rate.^{21–23} In recent investigations, the administration of less intensive drug regimens multiple times with peripheral blood stem cell support has resulted in decreased morbidity and mortality.²⁴

Other methods, such as intra-arterial therapy, intracavitary therapy, the use of biodegradable polymers intraoperatively impregnated with a chemotherapeutic agent (allowing a slow local release of the agent–wafer therapy), and direct intraparenchymal infusional therapy, are also being used in attempts to increase delivery to the local tumor site.^{25–31} Most recently, the use of circulating nanoparticles conjugated to tumor-targeting molecules and radioisotopes, chemotherapeutic agents, or other biological agents has been explored experimentally with some success.^{32,33} The first human adult cancer trials using therapeutic nanoparticles started in 2012.

Direct delivery to tumors via the infusion of toxins conjugated to agents that selectively bind tumor cells is under study in both adults and children with brain tumors. Such approaches, which use convection delivery techniques, are appealing yet potentially extremely toxic. Convection delivery has been shown to deliver agents quite extensively throughout the brain, but it is unclear whether the conjugated toxin is best delivered into the tumor or in the area around the tumor. The selectivity of tissue damage is also unclear. Although these are potentially useful techniques, their efficacy has not yet been clearly shown in either adults or children with brain tumors.

The mechanisms of drug resistance in primary CNS tumors are actively being defined.³⁴ Resistance to a given therapy may be an intrinsic property of a tumor or may be acquired after treatment. Tumors may acquire resistance by the loss of normal properties or by the amplification of existing mechanisms in the cells. Tumors may become cross-resistant to a whole group of drugs by a similar mechanism. Mechanisms of drug resistance include alterations in cell transport, the expression or amplification of genes like the multidrug resistance gene, and elevated intracellular levels of enzymes that interfere with the antitumor activity of a drug. The efficacy of the alkylator agents, at present one of the most widely used classes of drugs for the treatment of CNS tumors, is decreased by elevated levels of intracellular aldehyde dehydrogenase and glutathione or glutathione *S*-transferase.^{35–38} Similarly, intrinsic or acquired resistance to the nitrosoureas may be due to increased repair of DNA mediated by the O6-alkyl guanine DNA alkyl transferase protein or by elevated levels of thiol or glutathione *S*-transferases.^{35–38} A variety of techniques have been used in an attempt to overcome mechanisms of drug resistance, such as saturation of enzymes by alternative substrates or inactivation of cell resistance mechanisms by drugs, but none have shown a clear improvement in efficacy. One such approach under active study is the drug O6-benzylguanine, which depletes alkyl glutathione *S*-transferase levels. This enzyme-depleting drug was initially given with bischloroethyl-nitrosourea (BCNU) but is now also under study to increase sensitivity to temozolomide, as well as to improve the efficacy of alkylator-impregnated polymer wafers placed, after tumor resection, into the rim of the resection cavity.

In 1979, Goldie and Coldman proposed a mathematical model that related curability of a malignancy to the appearance of resistant cell lines.^{39,40} They proposed that control of a neoplasm was a function of various factors favoring resistance, including the tumor's spontaneous mutation rate. An outgrowth of this theory is the concept that a tumor is less likely to be resistant to multiple agents administered simultaneously than it is to be resistant to individual agents because cells are not given an opportunity to mutate and develop pleiotropic multiple-drug resistance. Additionally, if drugs are given over a relatively

short time, myelosuppression should be less because damage to hematopoietic precursor cells depends partially on the duration of exposure. This concept has been widely tested in pediatric brain tumor trials. The majority of ongoing chemotherapeutic studies are using a combination of drugs rather than single agents in attempts to improve efficacy.

In pediatrics, the applications of chemotherapy have not been limited to the development of means to improve survival. Given the well-documented toxicities of radiation, especially whole-brain irradiation, chemotherapy has also been employed in attempts to reduce the amount of radiotherapy required for disease control and in some cases to delay, if not obviate, the need for radiotherapy.^{4,5} Chemotherapy is now widely used for infants and young children with malignant brain tumors and for selected patients with low-grade tumors that are not surgically resectable without prohibitive morbidity.

50.4 Biological Therapy

Conventional chemotherapy has consisted predominantly of drugs that cause cytotoxic damage, with considerable systemic and, at times, CNS toxicity. In theory, the use of biological therapy, which in principle selectively targets specific molecular aspects of the tumor, results in a better therapeutic window and the ability to deliver therapy with less toxicity and greater efficacy. This concept of sparing normal cells by using molecularly based therapy is intriguing and in many ways is the “Holy Grail” of future cancer treatment. However, currently available biological agents may be less specific in the targets they hit than originally thought, and the molecular mechanisms disrupted may also be critical for normal cellular function in the brain or other organs. Concepts of cellular signaling, signal transduction pathways involved in cell regulation, proliferation, and survival are rapidly evolving.^{41–43} The role of proto-oncogenes and tumor suppressor genes in some brain tumors is just beginning to be characterized. Other factors involved in cancer development and growth, such as neoplastic angiogenesis and tumor invasion and migration, are also likely crucial in sustaining tumor growth and facilitating tumor spread. Agents have recently been developed that target critical mechanisms for tumor growth and are quickly entering the therapeutic arena. However, to date, none of them have demonstrated clear efficacy in regard to long-term control of pediatric brain tumors, and their short- and long-term toxicities are still being elucidated. At the same time, because of the unique mechanisms of action and promise of these agents, there is tremendous interest in integrating them, as rapidly as possible, into the standard treatment of childhood brain tumors.

Receptor tyrosine kinases are transmembrane receptor proteins that regulate many critical cellular processes, including proliferation and cell survival.^{43–45} A host of tyrosine protein kinase inhibitors have been developed in attempts to arrest growth signaling. In tumors, signaling may be activated by a variety of different mechanisms, including overexpression of the tyrosine kinase and gain of function; at times, the receptor is constitutively activated (especially in adult cases of GBM) even without the presence of a ligand.⁴⁵ A variety of receptor tyrosine kinases have been implicated in brain tumor pathogenesis and thus are potential targets for therapy. These include

platelet-derived growth factor, epidermal growth factor, vascular endothelial growth factor, insulin-like growth factor, and fibroblast growth factor.^{6,46} The biological agents that have been used include small-molecule inhibitors, which target the intercellular tyrosine kinase domains, and monoclonal antibodies, which act predominantly against growth factor ligands.

Platelet-derived growth factor receptor, which predominantly comprises two receptors (alpha and beta), has been shown to mediate cell signaling pathways involved in tumor proliferation, survival, invasion, and angiogenesis. Amplifications of platelet-derived growth factor have been demonstrated in pediatric high-grade gliomas, diffuse intrinsic brainstem gliomas, and medulloblastomas.^{47,48} Imatinib, a small-molecule inhibitor of BCR/ABL kinase, KIT, and platelet-derived growth factor receptor, has been found to be useful in a variety of different tumor types; however, studies of brain tumors in children have found it to be relatively ineffective,^{49,50} possibly because of its poor CNS penetrance. Other platelet-derived growth factor receptor inhibitors are presently in clinical trials.

Epidermal growth factor receptor comprises four members and is expressed on actively dividing cells, not only in brain tumors but also in brain neurogenic niches, such as the subventricular zone.^{43,44,51–53} Overexpression and amplification of epidermal growth factor receptor have been reported in pediatric high-grade gliomas and brain stem gliomas, as well as ependymomas, medulloblastomas, and low-grade gliomas.^{50–53} A variety of monoclonal antibody drugs have been in clinical trials, with small molecules used to target this family of receptors.^{54–56} Although these drugs have had a reasonable toxicity profile, their overall efficacy in regard to either tumor response or prolongation of survival has yet to be proved in pediatrics. Small-molecule inhibitors such as erlotinib, gefitinib, and lapatinib have also been fairly extensively tested against different types of pediatric brain tumors with some hints of efficacy, especially in specific subsets of patients, but no clear benefit in any specific tumor type.

Vascular endothelial growth factor, which comprises three receptors, has been identified as a potential target means to control tumor growth.⁵⁷ Vascular endothelial growth factor and vascular endothelial growth factor receptor increase with hypoxia, thus contributing to further angiogenesis, and act as another means to enhance tumor growth (oxygen tension is lower in rapidly progressing tumors than in normal tissue environments).⁵⁸ Monoclonal antibodies and small-molecule inhibitors of vascular endothelial growth factor ligands and receptors are in active development. Bevacizumab, a monoclonal antibody against vascular endothelial growth factor, has been approved for the treatment of recurrent malignant gliomas in adults.⁵⁹ Multiple studies have been undertaken in pediatrics without clear benefit in trials of adult malignant glioma or brain stem glioma.⁶⁰ There is evidence of efficacy of bevacizumab used in combination with irinotecan for pediatric low-grade gliomas.⁶¹ Some anti-angiogenic drugs have caused significant toxicities, such as difficult-to-control hypertension and proteinuria. A major risk associated with vascular endothelial growth factor receptor drugs, as well as possibly other growth factor receptor inhibitors affecting vasculature, has been intratumoral hemorrhage. To date, this risk has not been rate-limiting in pediatrics but remains significant nonetheless.

Downstream signal transduction pathways have also been targeted in pediatric brain tumors, especially the RAS/mitogen-activated protein kinase pathway, which plays an important role in tumor cell proliferation and survival.⁶² This RAS/RAF/MEK/ERK pathway offers a multitude of targets.⁶² Farnesyl transferase inhibitors, which inhibit the post-translational modification of RAS, have been studied but have not been found to be particularly effective.^{63,64} This may be because they are not selective as to the type of RAS abnormality in the tumor or do not adequately penetrate the tumor. RAF inhibitors, such as sorafenib, are in clinical trials.⁶⁵ Many RAF inhibitors actually are really multi-kinase inhibitors with activity against a variety of signal transduction targets. Although initially it was believed that drugs with great specificity would be most effective, there is a school of thought in developmental therapeutics that agents targeting multiple pathways, so-called multi-kinase inhibitors or “dirty kinase” inhibitors, may be even more effective. Sunitinib, like sorafenib, is a multi-kinase inhibitor that is in clinical trials.⁶⁶

The MEK inhibitors are still another class of drugs that are being actively evaluated. Because of the findings of *BRAF* oncogene activation in a high proportion of grade I (pilocytic) astrocytomas, there is significant interest in using such inhibitors in pediatrics.^{67,68} The phosphatidylinositol 3-kinase/protein kinase/mammalian target of rapamycin (mTOR) pathway is still another pathway being actively targeted in pediatric brain tumors.^{69,70} There has been enthusiasm concerning the use of rapamycin since initial experience in patients with tuberous sclerosis who harbored giant cell astrocytomas demonstrated an excellent response rate to rapamycin or a similar mTOR inhibitor drug, RAD001.⁷¹ How well this type of activity can be generalized to other brain tumors is under active study. Drugs specifically targeting P13 kinase activity are early in study, as are mTOR/P13k dual inhibitors.

The sonic hedgehog pathway seems to play a significant role in the pathogenesis of subsets of medulloblastomas. Sonic hedgehog inhibitors are actively being studied in this tumor type, and there is interest in potentially evaluating the efficacy of these drugs in other CNS tumors.⁷² Similarly, the Notch signaling pathway, which has demonstrated an important role in maintaining neural progenitor cells while inhibiting differentiation, has been noted to be dysregulated in gliomas, medulloblastomas, and ependymomas.^{73,74} γ -Secretase is one of the main proteolytic enzymes that cleaves the receptor and activates the Notch cascade. γ -Secretase inhibitors are a means to decrease Notch signaling.

Histone deacetylase inhibitors are being actively explored in pediatric brain tumors.⁷⁵ Histone deacetylase is involved in chromatin condensation and epigenetic silencing. Interestingly, one of the more commonly used anticonvulsants, valproic acid, is a histone deacetylase inhibitor.^{76–78} Valproic acid and other drugs, such as vorinostat and desipeptide, are in clinical trials. Thalidomide and a newer analogue, lenolidamide, are being used therapeutically because they exhibit activity against vascular endothelial growth factor as well as effects on basic fibroblast growth factor activity and immunomodulation.^{79,80} Lenolidamide is actively being studied in pediatric low-grade gliomas, and thalidomide has been used in a variety of multi-drug (metronomic) anticancer regimens.

Still another potential biological agent is retinoic acid, which acts as a tumor maturation drug.⁸¹ Retinoic acid has effects on both glial and medulloblastoma cells in vitro and is under active study as part of a multiagent approach including more standard chemotherapies in a variety of pediatric brain tumors, especially medulloblastoma.

Cell matrix adhesion is an additional target for pediatric brain tumor therapy.⁸² Integrins are mediators of cell adhesion to the extracellular matrix and play a significant role in the proper migration of cells through both the extracellular and intracellular environment. Integrins also interact with different receptor tyrosine kinases. Cilengitide is an integrin inhibitor that is actively being studied in both pediatric and adult brain tumors.

It should be cautioned that the use of these biological agents is extremely complex.^{6,7} Multiple feedback pathways exist, and it is likely that these agents will have to be used in combination with other biological agents or possibly more standard chemotherapy if they are to play a major role in the treatment of pediatric brain tumors. Specific subtypes of tumors that may have simpler molecular cascades, such as low-grade gliomas, may be more responsive to these biological agents used singly or in simple combinations. How these agents are best used in combination with conventional chemotherapy or radiation therapy is still being elucidated. Given that many of these same pathways are involved in normal brain development, the use of inhibitors has to be closely monitored because of their potential to cause neurodevelopmental toxicities.

50.5 Treatment of Specific Tumor Types with Chemotherapy

50.5.1 Medulloblastoma

Among all patients with childhood primary CNS tumors, the greatest experience with the use of chemotherapy has been in those with medulloblastoma. Prospective randomized studies have demonstrated that children with medulloblastoma can be broadly separated into two risk groups. New molecular markers, however, may change risk stratification significantly in the future.^{1,8,9,83} After treatment with surgery and radiotherapy, children with disseminated disease at the time of diagnosis, and possibly those whose tumors are large and involve the brainstem or are not amenable to total resection, have a poor prognosis, with an overall survival rate after radiation therapy alone of approximately 30 to 40% at 5 years (poor-risk patients). In contradistinction, those patients with localized disease at the time of diagnosis and whose tumors are amenable to aggressive resection have an approximately 50 to 60% survival rate at 5 years (average-risk patients). The addition of chemotherapy during and after radiotherapy has appeared to raise survival rates approximately 20% for both subgroups.

This has led to a generation of studies in which children with poor-risk medulloblastoma were treated with chemotherapy more aggressively in an attempt to improve survival, whereas patients with average-risk disease were treated according to protocols combining radiotherapy and chemotherapy, primarily intended to reduce the amount of radiotherapy given in an attempt to decrease the late effects of treatment. There is also a strong rationale for using chemotherapy as primary therapy for

Table 50.3 Children's Oncology Group ongoing or recently completed studies of chemotherapy for brain tumors

Tumor type	Study type	Chemotherapy	Radiotherapy
Average-risk medulloblastomas	Phase III	During and post-RT: VCR, CPDD, CCNU, Cyclo, VP-16	CSRT: 2,400 cGy versus 1,800 cGy; 5,500 cGy posterior fossa versus tumor site RT
Poor-risk medulloblastomas	Phase III	Carbo during RT versus no Carbo with and without retinoic acid	CSRT: 3,600 cGy; 5,940 cGy local RT
Infantile malignant tumors	Phase I/II	High-dose chemotherapy with Cyclo, VCR, CPDD, VP-16, and thiotepa/carboplatin with PSCR with and without MTX	? Post-Rx RT
Low-grade gliomas	Phase III	Carbo/VCR versus CCNU, PCB, 6-TG, VCR	No RT
Low-grade gliomas	Phase II	Carbo/VCR/temozolomide	No RT
Ependymomas	Phase II	Pre-RT, second-look surgery: Carbo, VCR, VP-16, CPDD, Cyclo	Local RT
Ependymomas	Phase III	Carbo, VP-16, Cyclo versus no chemo for anaplastic post-RT	Local RT
High-grade gliomas	Phase II	Pre-RT chemotherapy/ biological therapy	Local RT
Nongerminomatous germ cell tumors	Phase II	Pre-RT ifosfamide, Carbo, VP-16, ifosfamide, thiotepa	?

Abbreviations: Carbo, carboplatin; CPDD, cisplatin; CSRT, craniospinal RT; Cyclo, cyclophosphamide; MTX, methotrexate; PCB, procarbazine; PSCR, peripheral stem cell rescue; RT, radiotherapy; 6-TG, 6-thioguanine; VCR, vincristine; VP-16, etoposide.

some children with medulloblastoma (especially very young children) to allow deferral and, occasionally, avoidance of radiotherapy (► Table 50.3).

Recurrent Disease

Multiple reports have documented the objective response of recurrent medulloblastoma to a variety of different chemotherapeutic agents, including cisplatin (CPDD), carboplatin, cyclophosphamide, and etoposide, both singly and in combination regimens.⁸⁴⁻⁹¹ However, despite response rates as high as 80% in some studies, durable survival has been rarely documented after conventional doses of chemotherapy. In addition, there are few, if any, long-term survivors noted in series describing children who failed initial treatment with surgery and craniospinal radiotherapy treated with conventional doses of chemotherapy. High-dose chemotherapy supplemented with autologous bone marrow rescue has been used in children with recurrent medulloblastoma.^{22,23,92-95} A high rate of response has been documented in such studies; however, preliminary studies also showed a high rate of treatment-related morbidity. For example, the combination of high-dose thiotepa, etoposide, and carboplatin was used in 23 patients with recurrent medulloblastoma.^{22,23,92} Three patients in this series died of treatment-related toxicity. However, three patients survived without evidence of progression at a median of 36 months from treatment (range, 10 to 63 months). Those patients who did the best after high-dose chemotherapy were those who had minimal residual disease before the use of chemotherapy and no evidence of leptomeningeal dissemination. Other centers, using other high-dose chemotherapeutic regimens, have not reported as many patients with long-term disease control.⁹³⁻⁹⁶ It is likely that even if high-dose chemotherapeutic regimens are documented to be efficacious in some children with recurrent medulloblastoma, the autologous bone marrow rescue approach will be replaced by studies using high-dose chemotherapy supported by peripheral stem cell rescue.

Biological therapy for patients with recurrent medulloblastoma has primarily focused on the use of sonic hedgehog inhibitors, and responses, although primarily transient, have been noted to date.⁹² Notch pathway inhibitors have also been used.^{73,74}

Newly Diagnosed Disease

Based on studies that demonstrated objective responses to chemotherapy in children with recurrent medulloblastoma, post-surgery trials have been undertaken to evaluate the efficacy of chemotherapy, when added to radiotherapy, for children with newly diagnosed disease (► Table 50.4).⁹⁷⁻¹¹²

Two large prospective randomized trials were performed independently by the Children's Cancer Group (CCG) and the International Society of Pediatric Oncology (SIOP).^{1,83} In both studies, patients were randomized to receive radiation therapy alone (3,600 centigray [cGy] of craniospinal irradiation plus local tumor boost to a total dose of 5,400 to 5,600 cGy to the tumor site) or identical radiation therapy plus vincristine (VCR) during the radiation and postradiation therapy cycles of 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) and VCR. For children in the CCG trial, the postradiation chemotherapy regimen also included prednisone. These trials demonstrated for the first time a statistical benefit for the addition of chemotherapy in children with poor-risk posterior fossa medulloblastoma. In the CCG trial, the estimated 5-year progression-free survival (PFS) rate was 59% for children treated with irradiation and chemotherapy and 50% for those who were treated with irradiation alone. However, in patients with a larger tumor bulk at the time of initial surgery and those with the most extensive tumor, there was a demonstrable benefit from the addition of chemotherapy because the event-free survival (EFS) rate was 48% for those receiving chemotherapy, whereas it was 0% for those treated with radiation alone.

While these prospective randomized trials were being performed, other single-institution trials were also being

Table 50.4 Selected adjuvant chemotherapy trials in children with medulloblastoma

Study (No. of patients)	Type of trial	Dose of CSRT (cGy)	Drugs used	Outcome
McIntosh et al ⁹⁷ (21)	Single arm; all risks	WB 3,925; spinal 3,300	VCR; Cyclo	PFS 5 years 81%
Evans et al ¹ (179)	Randomized; all risks	WB 3,600; spinal 3,600	CCNU/VCR; prednisone versus RT alone	PFS 5 years 60%, w/CHT (high-risk 46% CHT versus 0% no CHT)
Tait et al ⁸³ (251)	Randomized; all risks	WB 3,500–4,500; spinal 3,000–3,500	CCNU; VCR versus RT alone	PFS 5 years 53%
Bailey et al ¹⁰² (364)	Randomized; all risks	WB 3,500; spinal 3,500 versus WB 2,500; spinal 2,500	Pre-RT VCR; PCB; MTX versus VCR; CCNU post-RT	EFS 5 years pre-RT plus no post-RT 2,500 cGy 41% ± 8%

completed. McIntosh and colleagues⁹⁷ reported that 81% of 21 children treated with postradiation therapy cyclophosphamide and VCR were alive and free of disease at a median of 6 years after diagnosis. Packer and colleagues reported that in a three-center trial evaluating 63 children with posterior fossa medulloblastomas, the PFS rate at 5 years was 85.6%.^{98,99} For eligibility in the latter study, children had to be older than 3 years and must have had subtotal resection, evidence of metastatic disease at the time of diagnosis, and/or brainstem involvement. Patients with metastatic disease at the time of diagnosis had a

5-year PFS rate of 67.15% versus 90.6% for those with localized disease.

A study completed by the CCG prospectively treated children who had so-called poor-risk disease with craniospinal and local boost radiotherapy and concomitant VCR chemotherapy during the radiation and eight 6-week cycles of postradiation CCNU and VCR and CPDD, or with 8-drugs-in-1-day therapy for two cycles before irradiation, then craniospinal and local boost radiation, then eight postradiation therapy cycles of 8-drugs-in-1-day therapy.¹⁰⁰ The 3-year EFS rate for the group as a whole

was 57%. However, those children who received the control arm of CCNU and VCR had a statistically higher 5-year EFS rate than did those who received pre- and postradiation 8-drugs-in-1-day therapy (3-year PFS rates of 62.8% vs. 48.8%). A multicenter randomized trial performed by the SIOP that involved 364 children with biopsy-proven medulloblastoma could not demonstrate a benefit for the use of preradiation chemotherapy with a regimen of methotrexate, procarbazine, and VCR.¹⁰² A study performed by the German Cooperative Group, in which an even more aggressive approach to preradiation chemotherapy was used, could not show benefit from treatment with chemotherapy. There was also poorer disease control in the children with localized disease who received preradiation chemotherapy than in those treated with radiation plus postradiation CCNU, VCR, and CPDD chemotherapy.¹⁰⁵ In another randomized trial, the Pediatric Oncology Group (POG) compared postradiation nitrogen mustard, VCR, prednisone, and procarbazine as adjuvant therapy with craniospinal irradiation alone.¹⁰² The 5-year EFS rate for the group receiving radiotherapy and chemotherapy was 68%, compared with 57% for those receiving irradiation alone. Given the number of patients entered, however, this difference was not statistically significant.

The results of another SIOP trial, PNET-3, compared the outcomes of patients who had nondisseminated disease treated with radiotherapy alone (3,600 cGy of craniospinal radiation) with the outcomes of patients who received four cycles of preradiation chemotherapy with oral VP-16, VCR, carboplatin, and cyclophosphamide.¹⁰⁸ Overall survival did not differ statistically between the groups, but the EFS rate at 5 years was lower in those who received radiotherapy alone (5-year EFS rate of 74.2% for those receiving radiation plus chemotherapy vs. 59.8% for those who received radiotherapy alone; $p = 0.0928$).

Although prospective randomized studies comparing 3,600 cGy of craniospinal radiotherapy with reduced-dose craniospinal radiotherapy and adjuvant chemotherapy have never been performed, one of the most compelling studies was one by the Children's Oncology Group (COG) that used 2,340 cGy of craniospinal radiotherapy and either of two chemotherapy regimens: CCNU, CPDD, and VCR or cyclophosphamide, CPDD, and VCR.¹⁰⁹ In both treatment arms, VCR was used during radiotherapy. In 379 evaluable patients, the 5-year PFS rate was $86\% \pm 9\%$; there was no difference between the two chemotherapeutic regimens.¹⁰⁹ A study using higher-dose chemotherapy following radiotherapy, supported by peripheral stem cell rescue, demonstrated a similar rate of PFS.¹¹⁰ A French study also demonstrated that the dose of craniospinal radiotherapy could be reduced to 2,400 cGy if chemotherapy was added.¹¹¹

These studies, taken in total, suggest that adjuvant chemotherapy is of benefit in children with medulloblastoma. The trials, to date, that have used preradiation chemotherapy have shown no clear advantage for the addition of such chemotherapy in children with more extensive disease at diagnosis and poorer survival for those with average-risk disease compared with immediate postoperative radiotherapy and adjuvant chemotherapy during and after radiotherapy.¹¹² Preradiation chemotherapy may be better than treatment with radiotherapy alone for patients with disseminated disease, but it is unclear whether it is as effective as treatment with radiotherapy plus chemotherapy during or after irradiation. It is paradoxical that children with average-risk disease treated with radiation alone

seem to have no better survival rates or, in some studies, poorer survival rates than do children with poor-risk disease treated with radiation plus chemotherapy.¹⁰⁸

For children with high-risk medulloblastoma, another potential use of chemotherapy is to intensify treatment, either by administering chemotherapy during radiation (carboplatin) to act as a radiosensitizer or by increasing the dose of postradiation chemotherapy by means of peripheral stem cell rescue. Both approaches have shown possible benefit.

Treatment of Infants

Infants are yet another subset of children with medulloblastoma who have been extensively treated with chemotherapy.^{113,114} Most studies indicate that the prognosis for children in whom medulloblastoma is diagnosed in the first 3 to 4 years of life is poorer than that in older children, independently of whether they are treated with radiation alone or radiation in conjunction with chemotherapy. Because cranial irradiation in young children has been associated with severe adverse delayed toxicities, including intellectual deterioration and endocrinologic (especially growth) sequelae, multiple studies dating back to the 1970s have utilized postsurgical chemotherapy, with delayed or no radiotherapy, for infants with medulloblastoma. In an early study, the use of mechlorethamine, Oncovin (VCR), procarbazine, and prednisone (MOPP) chemotherapy in 13 children younger than 36 months of age with medulloblastoma resulted in a PFS rate of 55%.¹¹⁵ The largest early experience has been that of the POG, which used a four-drug regimen of VCR, cyclophosphamide, CPDD, and etoposide in children younger than 3 years of age with medulloblastoma until they were 36 months of age, or for at least 12 months.⁵ In this protocol, delayed irradiation was given upon completion of chemotherapy, and the median time to relapse in patients with medulloblastoma was 9 months; 34% of patients remained progression-free for a median of 2 years from diagnosis. No patient had a relapse beyond 26 months from diagnosis, raising the issue of the necessity of irradiation in those with a complete response. The CCG has used the 8-drugs-in-1-day chemotherapy regimen for children younger than 18 months of age with newly diagnosed medulloblastoma.¹¹³ In this study, radiation therapy was not routinely employed in those children with a complete response, and the 3-year PFS rate was 22%. The German Cooperative Group has used four cycles of an aggressive regimen of ifosfamide, methotrexate, CPDD, VCR, and intravenous cytosine arabinoside (ara-C) for infants with medulloblastoma.¹¹⁶ The treatment of patients with localized disease at diagnosis resulted in a 2-year disease-free survival rate of 92% without radiotherapy. In contrast, in all patients with disseminated disease, their disease ultimately progressed during or after chemotherapy treatment.

In an even more aggressive approach, investigators at Memorial Sloan-Kettering Cancer Center in New York City and participating institutions treated children younger than 3 years who had localized medulloblastoma and children between 3 and 6 years of age who had disseminated medulloblastoma with five cycles of induction chemotherapy (CPDD, high-dose cyclophosphamide, etoposide, and VCR) followed by a consolidation cycle of myeloablative chemotherapy (thiotepa, etoposide, and carboplatin), supported by autologous bone marrow rescue.¹¹⁷ In 13

patients, the 5-year EFS and overall survival rates were 51% and 61%, respectively.

Still another approach is the addition of intrathecal chemotherapy to systemic chemotherapy. Infants with nondisseminated medulloblastoma treated with high-dose intravenous and intraventricular methotrexate and cytosine arabinoside, coupled with other systemic chemotherapeutic agents, demonstrated a nearly 60% 5-year PFS rate without receiving radiotherapy.^{118–120} This study and a subsequent follow-up study achieved a disease-free survival rate of greater than 80% for those with nodular or desmoplastic medulloblastoma, demonstrating both the better prognosis for the subgroup of patients with that variant of medulloblastoma and that some infants can be treated with chemotherapy alone after surgery. Methotrexate has been associated with a high rate of leukoencephalopathy, raising issues over the long-term benefits of such approaches. The ability of chemotherapy alone to control disseminated disease in infants has never been shown. Other approaches are coupling biological agents, including retinoic acid and SAHA (suberoyl anilide hydroxamic acid), with multiagent chemotherapy to improve disease control.

50.5.2 Other Primitive Neuroectodermal Tumors

The chemotherapy used for children with primitive neuroectodermal tumors (PNETs) arising outside the posterior fossa, including pineoblastomas, has mirrored that used for children with medulloblastomas. Data suggest that children with non-posterior fossa PNETs have a poorer prognosis than those with medulloblastomas, possibly because of their younger age at the time of diagnosis or because such tumors (especially pineoblastomas) are frequently disseminated early in the course of illness.^{121–123} Also, non-posterior fossa tumors are genomically different from medulloblastomas.

The role of adjuvant chemotherapy for children with non-posterior fossa PNETs has not been well demonstrated.^{121,122} This is partially due to the relatively small numbers of patients available for study. In the CCG trial comparing pre- and post-radiation chemotherapy with the 8-drugs-in-1-day regimen versus treatment with radiation therapy plus CCNU and VCR, children with both pineal PNETs and non-posterior fossa, non-pineal PNETs were treated. For the 44 patients with supratentorial PNETs, the PFS rate was 45.8%. In addition, 25 children with pineal tumors were treated. Eight were younger than 18 months and were nonrandomly treated with the 8-drugs-in-1-day chemotherapy regimen. The remaining 17 patients were randomized between the two treatments. All infants in this study developed progressive disease at a median of 4 months from the start of treatment. In the 17 older patients, the overall 3-year PFS rate was 61.13%. The numbers in this study are too small to evaluate the relative efficacy of either of the two adjuvant chemotherapy regimens. In the SIOP study, 25 children with supratentorial PNETs were treated with chemotherapy alone, and 24 had a relapse at a median of 5.5 months. In a study in older children, radiotherapy plus CCNU, VCR, and CDDP chemotherapy resulted in an approximately 50% rate of disease control.¹²⁴ High-dose chemotherapy with peripheral stem cell rescue using cyclophosphamide, CPDD, and VCR following

radiotherapy has also been tried in this population, with at least evidence that such an approach is feasible.¹⁹ Given the poor outcome of children with non-posterior fossa PNETs, most investigators are using some form of chemotherapy in addition to radiation therapy.

50.5.3 High-Grade Gliomas

The issue of the efficacy of chemotherapy for malignant gliomas in childhood remains somewhat unsettled.³ To date, chemotherapeutic trials for pediatric malignant gliomas have largely been initiated based on the encouraging results observed for a particular drug or regimen first investigated in adult malignant gliomas. However, it is now becoming clear that adult GBMs are molecularly heterogeneous and quite distinct from pediatric lesions.^{125,126} Thus, it is very likely that future pediatric trials will need to be designed and tailored more specifically for the molecular targets uniquely represented in the pediatric form of the disease. The molecular genetic alterations of both childhood and adult malignant gliomas are still being elucidated, but emerging evidence now demonstrates that malignant astrocytic tumors arising in childhood are more likely to have *TP53* mutations and thus a genetic composition different from that of the neoplasms of adulthood, which are believed to go through a cascade of genetic changes as they progress from low-grade to high-grade malignancies.¹²⁷ This may in part explain the differences, if they exist, between the sensitivities to chemotherapy of adult and pediatric malignant gliomas. For example, adult patients with GBM demonstrated a clear survival benefit with the addition of temozolomide to standard-dose irradiation; however, a similar benefit was not demonstrated in an identical pediatric malignant glioma trial.¹²⁸ Molecularly targeted therapy against alterations more commonly observed in high-grade pediatric gliomas, such as *PDGFRA* amplification, are under way at some centers. Other strategies, such as the combination of anti-angiogenesis inhibitors or other novel biological agents with radiation, are being investigated. Clinical trials, as noted in ► Fig. 50.1, are ongoing to better define the role of chemotherapy in high-grade glioma management.

Recurrent Disease

At the time of recurrence, malignant gliomas may transiently respond to chemotherapeutic agents. Interpretations of chemotherapy trials are difficult, especially in adult series, because many trials combine patients with objective neuroradiographic response together with those who have disease stabilization, considering both groups as “responders.”^{129–131} The nitrosoureas singly or in combination with other drugs, such as procarbazine and VCR, have been the most extensively studied drugs in adult Phase II trials; overall objective response rates usually have ranged from 10 to 20% (although some report transient benefit in as many as 75% of patients). Median time to progression in most series, which may be a better marker of efficacy, is usually less than 6 months, with most series documenting disease progression by 20 to 25 weeks after the initiation of treatment. Studies in purely pediatric populations with recurrent malignant gliomas have been undertaken less commonly. Drugs that have been evaluated include VCR, procarbazine, intravenous etoposide, oral etoposide, BCNU, CCNU, CPDD,

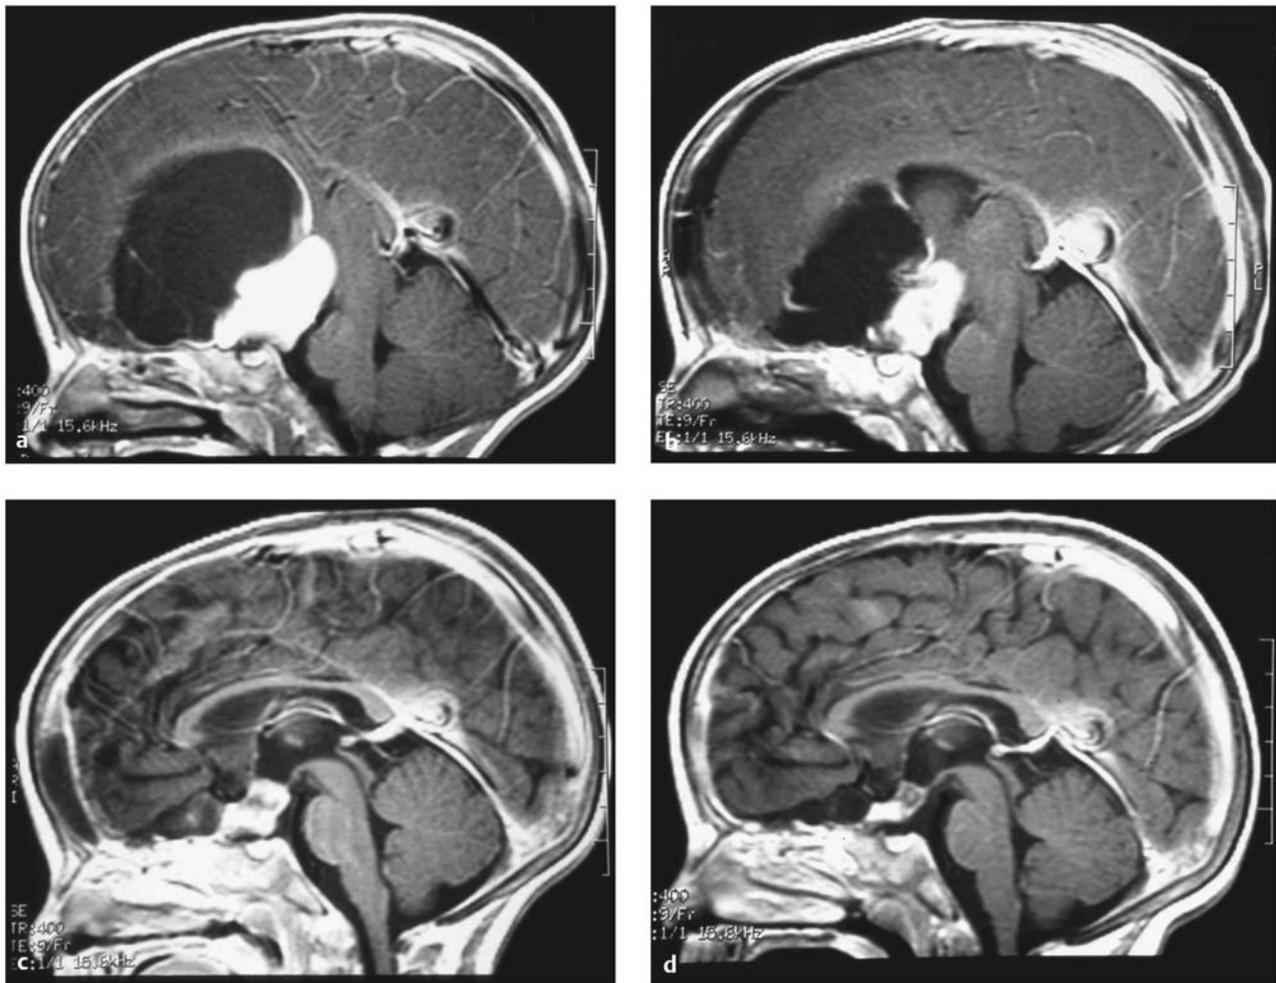

Fig. 50.1 Sagittal magnetic resonance imaging after gadolinium (a) at diagnosis, (b) following surgery, (c) at 3 months, and (d) at 12 months after treatment with carboplatin and vincristine in an 11-month-old child without neurofibromatosis with a diencephalic pilocytic astrocytoma.

cyclophosphamide, carboplatin, irinotecan, and thiotepa as single agents or in combination with another agent, such as ifosfamide or high-dose cytosine arabinoside.^{132–150} These studies have shown objective response rates ranging from 0 to 50%, with most studies reporting tumor shrinkage in 10% of patients or fewer. As in adult trials, even in those series reporting a higher rate of response, the median time to progression has been less than 1 year and usually 6 months or less.

Temozolomide is an oral alkylating agent that has been well tolerated and has shown promising but mixed results in adults and children with recurrent high-grade gliomas.^{151–153} In adult trials, objective responses plus stable disease were reported in as many as 67% of patients with recurrent grade II tumors. For patients with GBM, similar overall “responses” were noted, but the duration of response was shorter. Experience in pediatric patients has been less extensive, with a greater variability noted in pediatric series, with objective responses ranging from 0% in a CCG series to as high as 50% in a smaller limited-institution trial.¹⁵¹ One approach to increase the efficacy of temozolomide and other drugs that alkylate DNA in the O6 position, such as the nitrosoureas and procarbazine, is to couple such treatments with drugs that bind to the DNA repair protein O6-alkylguanine

DNA-alkyltransferase. One such drug is O6-benzylguanine. Despite encouraging preliminary data, the most recent pediatric clinical trial for refractory high-grade gliomas using the combination of temozolomide and O6-benzylguanine failed to demonstrate efficacy.¹⁵⁴

There has been interest in the use of higher doses of chemotherapy for children with malignant gliomas supplemented by either autologous bone marrow rescue or peripheral stem cell rescue.^{22,155–157} Thiotepa and etoposide have been used at high doses for children with malignant gliomas. Objective responses to therapy were noted in 6 of the first 10 patients treated. Later studies combining high-dose BCNU with thiotepa and etoposide or high-dose carboplatin with thiotepa and etoposide disclosed a similar overall response rate in a larger group of patients. These studies also encouragingly disclosed a small subgroup of children with prolonged survival, including children with anaplastic gliomas and those with GBMs. These results were tempered by a toxic mortality rate of nearly 20% in the preliminary studies. Other groups using different chemotherapeutic agents, such as busulfan and thiotepa or melphalan-based regimens, have not been able to demonstrate such high response rates or prolonged responses to chemotherapy.^{22,155–157} The reasons for

these disparities in studies are unclear; however, it does seem that patients with minimal residual disease before treatment with high-dose chemotherapy (those with tumors that could be debulked before chemotherapy) were the most likely to derive a prolonged benefit from treatment.

Newly Diagnosed Disease

Despite multiple single-institution trials and prospective randomized studies, the value of adjuvant chemotherapy for adults with malignant gliomas is far from dramatic. Chemotherapy for adults, when given as an adjuvant with or after radiation therapy, produces a modest prolongation in median survival but has not clearly been shown to improve the likelihood of long-term survival.^{158–163} A meta-analysis of major adjuvant chemotherapy trials concluded that there was a 10% increase in survival at 1 year and an 8.6% survival advantage at 2 years for adults who had GBM treated with chemotherapy and radiotherapy compared with those treated with irradiation alone.^{164,165}

The study that has suggested most strongly that adjuvant chemotherapy is of benefit for children with high-grade gliomas was completed by the CCG in 1982.³ In this trial, the addition of CCNU and VCR chemotherapy, during and after radiotherapy, increased survival compared with treatment with radiation alone. Of the children in this randomized trial who received radiotherapy and adjuvant chemotherapy, 46% were alive and free of disease 5 years following treatment versus 18% of those treated with postsurgery radiotherapy alone. The benefit of chemotherapy was statistically significant for children with GBM.

In a follow-up study, the CCG compared pre- and postradiation chemotherapy with the 8-drugs-in-1-day regimen versus therapy with irradiation and CCNU and VCR.¹⁶⁶ No survival advantage was shown for the children treated with pre- and post-radiation 8-drugs-in-1-therapy in comparison with those treated with adjuvant CCNU and VCR. Overall, the survival rates for children with anaplastic gliomas and those with GBM were somewhat lower in the most recent CCG trial, but approximately 30% of children with anaplastic gliomas and 20% of children with GBM were alive and free of disease 5 years following treatment. A statistical comparison of these two trials showed no difference in overall survival between them.¹⁶⁷ A more recent review of this information suggested that some of the children considered to have high-grade gliomas in the first CCG trial actually had low-grade gliomas. However, even when the pathologic materials were reviewed again, there was a statistical benefit for the addition of CCNU and VCR for children with GBM.

Given the equivocal results of adjuvant trials and the preliminary results of high-dose chemotherapy for recurrent high-grade glioma, studies are presently ongoing using high-dose chemotherapy either before or following radiation therapy for children with anaplastic gliomas (primarily subtotally resected tumors) and children with GBM. A CCG trial that used couplets of agents, including cyclophosphamide and VCR, ifosfamide and VCR, and carboplatin and VCR, before irradiation demonstrated an overall poor objective response rate of less than 20%.¹⁶⁸ Alternatively, trials of chemotherapy during radiation therapy with agents like temozolomide in patients with newly diagnosed disease are ongoing. However, temozolomide alone given

concurrently with radiation on a daily low-dose schedule followed by a standard dose and scheduled maintenance temozolomide failed to improve survival in the most recent COG trial for newly diagnosed pediatric malignant gliomas.¹²⁸ Newer biological agents, such as inhibitors of tyrosine kinase receptors (anti-EGFR and anti-PDGFR), epigenetic modifying agents such as histone deacetylase (HDAC) inhibitors, anti-angiogenesis agents (e.g., bevacizumab, cilengitide), and cell signal-disrupting agents, have also been coupled with irradiation in attempts to improve disease control.

50.5.4 Brainstem Gliomas

The majority of children with brainstem gliomas have diffuse infiltrating lesions that primarily involve the pons and result in death within 18 months of diagnosis. Because of this poor survival rate, chemotherapy has been used in children with both newly diagnosed and recurrent brainstem gliomas. Such studies are still ongoing, but there has been increased interest in using chemotherapy during radiotherapy for patients with newly diagnosed disease.

Recurrent Disease

At the time of recurrence, a variety of single agents investigated in patients with high-grade gliomas (e.g., intravenous carboplatin, cisplatin, and etoposide; oral thiopeta and CCNU) have resulted in responses in only 0 to 20% of patients.^{169–173} Temozolomide has also been used, with disappointing results. Furthermore, in the majority of cases, even if partial tumor shrinkage occurred, the response was relatively short. Oral etoposide resulted in a response in 4 of 12 children with recurrent brainstem gliomas.¹⁶⁹ In addition, a variety of drug combinations have been tried without clear benefit.

Newly Diagnosed Disease

Adjuvant postradiation chemotherapy has been poorly studied in children with brainstem gliomas. In one of the few randomized prospective studies performed to date, the addition of postradiation CCNU and VCR did not improve the length or frequency of disease-free survival in comparison with radiotherapy alone.¹⁷⁴ The median PFS in this study of 79 children with brainstem gliomas was 7 months for those receiving radiation therapy alone and 6 months for those treated with radiation and chemotherapy.

Chemotherapy has been used before irradiation in an attempt both to identify active agents and to improve survival. One study of cisplatin and cyclophosphamide in 32 children demonstrated that such therapy could be delivered before radiotherapy but resulted in a poor overall response rate (3 of 32, or 9%) with no improvement in survival.¹⁷⁵ Carboplatin given before radiotherapy resulted in responses in 2 of 27 patients; the median overall survival in this series was 9 months.¹⁷¹ In a CCG trial, treatment with cisplatin, etoposide, cyclophosphamide, and VCR or with carboplatin, etoposide, and VCR before irradiation resulted in few objective responses and no apparent improvement in survival.¹⁷⁶ Another trial coupled carboplatin with a bradykinin agonist during radiotherapy to improve drug delivery but did not show apparent improved survival. High-dose,

multiagent chemotherapy, such as that used in protocols designed for patients with high-grade cortical gliomas, has been attempted in this population before irradiation. However, because of inordinate toxicity and a lack of clear efficacy, these studies were aborted.¹⁷³⁻¹⁷⁵ Other studies are evaluating the efficacy of chemotherapy, biological agents, and novel radiosensitizers during and after radiation in attempts to improve survival. To date, no agent has shown clear benefit.

Interferon has been used in children with both recurrent and newly diagnosed brainstem gliomas.¹⁷⁶⁻¹⁷⁸ Nagai and Arai¹⁷⁷ demonstrated objective responses in 8 of 20 patients with recurrent high-grade gliomas after intrathecal or intratumoral infusion of interferon- β . Interferon- β resulted in objective tumor responses in 2 of 9 children with recurrent brainstem gliomas and prolonged disease stabilization in 2 patients in another series.¹⁷⁶ However, a follow-up study of interferon- β , given both during and following irradiation for patients with newly diagnosed brainstem gliomas, did not demonstrate increased efficacy.¹⁷⁸ In this latter study, 32 children were treated, and 30 of 32 developed progressive disease at a median of 5 months from diagnosis. In contrast, a study by Wakabayashi et al¹⁷⁹ treated 16 pediatric patients who had a diagnosis of brainstem glioma with interferon- β , ACNU ([1-(4-amino-2-methyl-5-pyrimidinyl)methyl-3-(2-chloroethyl)-3-nitrosourea hydrochloride]), and radiation therapy. Of 8 patients in this series with diffuse intrinsic tumors, 7 were reported to have a complete or partial response to treatment, with a median overall survival of 15.7 months. Surprisingly, in the study of Wakabayashi et al, the best survival rate was seen in patients with diffuse intrinsic tumors. The role of interferon- β for patients with brainstem gliomas thus remains unclear, but studies continue to be performed with this agent and other forms of immunotherapy.

50.5.5 Low-Grade Gliomas

Low-grade gliomas constitute the majority of childhood brain tumors. Until the 1980s, chemotherapy was used sparingly in children with recurrent and newly diagnosed low-grade gliomas.^{180,181} Most studies were performed primarily in children with diencephalic tumors. Similar outcomes, in smaller numbers of patients, have been reported in children with tumors in other CNS sites, including the brainstem. For exophytic pilocytic astrocytomas, a variety of drugs demonstrated efficacy against recurrent tumors, although in most cases, these regimens were used in only a small group of patients.¹⁸¹⁻¹⁸⁷ Drugs or drug combinations that have been used and found to be somewhat effective in children with recurrent low-grade gliomas include actinomycin and vincristine, carboplatin alone, carboplatin and vincristine, vinblastine, vinorelbine and carboplatin, etoposide, etoposide and cisplatin, temozolomide, and multidrug regimens, such as TPCV (CCNU, procarbazine, vincristine, 6-thioguanine, and dibromodulcitol). Most studies using single-agent temozolomide, vinorelbine, or carboplatin reported stable disease, although the regimen of carboplatin and vincristine resulted in objective tumor shrinkage in 9 of 19 patients.¹⁸⁶

Biological agents have recently been incorporated into the therapy of recurrent low-grade gliomas. Bevacizumab plus irinotecan demonstrated a 30 to 60% response rate, at times associated with visual or neurologic improvement, in children with multiply recurrent low-grade gliomas.⁶¹ Drugs targeting the

RAS/MAPK pathway are being actively explored, stimulated by the discovery of *BRAF* mutations in the majority of children with pilocytic astrocytomas.⁶² Inhibition of *BRAF* and *MEK*, as well as inhibitors of *mTOR*, are under active study.

Newly Diagnosed Disease

The role of chemotherapy for children with newly diagnosed low-grade gliomas is established, although the optimal regimen remains to be determined. In attempts to decrease the potential long-term sequelae of radiation therapy, chemotherapy has been used to at least delay, if not obviate, the need for radiation therapy. The largest early experience with chemotherapy was with the combination of actinomycin D and VCR.¹⁸⁸ In a series of 30 patients younger than 5 years of age with newly diagnosed, progressive visual pathway gliomas, 80% of the children were shown to have at least disease stabilization while receiving chemotherapy (an overall objective response was seen in 20% of patients). This stabilization lasted for a mean of 3 years and resulted in the requirement for radiation at a median age of 4.5 instead of 1.5 years. Subsequently, the combination of carboplatin and VCR has been widely used for children with newly diagnosed or progressive low-grade gliomas at any site in the nervous system.¹⁸⁷ The overall response rate after treatment with carboplatin and VCR was 60% (► Fig. 50.1). More than 90% of patients, independently of the location of their tumor in the nervous system, experienced at least disease stabilization with this regimen. In a series of 78 patients, the PFS rate with the two-drug regimen was 68% at 3 years, and therapy was shown to benefit both patients with diencephalic tumors and those with progressive low-grade brainstem tumors.

Other agents and drug combinations have been used in patients with newly diagnosed disease. The TPCV combination of CCNU, VCR, 6-thioguanine, procarbazine, and dibromodulcitol demonstrated either stabilization or objective response in 12 of 15 patients with newly diagnosed low-grade tumors.¹⁸⁹ CPDD and etoposide resulted in a 70% response rate in 34 patients with progressive low-grade gliomas and a PFS rate of 78% at 3 years.¹⁹⁰ Similar results have been reported with even more aggressive multiagent regimens containing CPDD and cyclophosphamide used by the French Society of Pediatric Oncology. A COG randomized study in children younger than 10 years of age with progressive low-grade gliomas, comparing the carboplatin and vincristine regimen with the TPCV regimen, found a borderline statistical advantage at 5 years for the TPCV regimen (EFS 35% \pm 4.7% for carboplatin/vincristine vs. 48% \pm 4.8% for TPCV).¹⁹¹ Secondary tumors may be more likely after the TPCV regimen. A recently completed study adding temozolomide to the carboplatin and vincristine regimen has shown impressive 3-year disease control. In all these studies, children with neurofibromatosis type 1 (NF-1) are excluded from the alkylator-based regimens because of concerns over an increased incidence of mutagenesis. Children with NF-1 have a better than 50% rate of disease control at 5 years after treatment with carboplatin and vincristine. A treatment-limiting complication with the carboplatin and vincristine regimen is drug allergy in up to 30% of those being treated.

There is substantial evidence that chemotherapy can result in at least transient disease stabilization and delay the need for radiotherapy. However, the short- and long-term sequelae of

more aggressive regimens, such as hearing loss, an increased risk for infection, and mutagenesis, need to be carefully assessed, especially if disease control is similar with less aggressive chemotherapeutic treatment.¹⁹² This is significant for very young children with large, diffuse tumors. The role for chemotherapy in older children is less clear. There is no evidence to support combining chemotherapy with radiation therapy in children with low-grade tumors.

50.5.6 Oligodendrogliomas

Information on the utility of chemotherapy for children with either newly diagnosed or recurrent oligodendrogliomas is essentially nonexistent. Given the rarity of this tumor in the pediatric population, most studies have included children with oligodendrogliomas either in trials of patients with malignant gliomas or, alternatively, in studies of children with low-grade gliomas. The combination of procarbazine, CCNU, and VCR has demonstrated a high response rate in adults with recurrent malignant oligodendrogliomas.¹⁹³ One report of 37 pediatric patients from a single institution indicated that gross total resection and age older than 3 years correlated with improved PFS, yet neither postoperative chemotherapy nor irradiation was associated with outcome.¹⁹⁴

50.5.7 Ependymomas

The value of chemotherapy for children with ependymomas is unclear. In most series, more than 50% of children with either benign or malignant ependymomas have disease recurrence, and a variety of chemotherapeutic agents have been used in an attempt to control disease. Such therapy is being actively explored in national trials (► Table 50.3).

Recurrent Disease

The nitrosoureas have been variably associated with response in the setting of recurrence. Cisplatin has been reported to result in objective responses in from 30 to 60% of patients at the time of recurrence.^{136,137,143,194} In one study, aggressive treatment with chemotherapy following surgical re-resection and then further chemotherapy resulted in prolonged disease control in approximately 30% of children with locally recurrent ependymomas.¹⁹⁵ Other drugs have shown variable degrees of efficacy.

Newly Diagnosed Disease

In the adjuvant setting, a benefit of chemotherapy has never been shown for children with ependymomas. In a small series of patients, CCNU and VCR during and after radiotherapy did not result in improved survival in comparison with radiation therapy alone.¹⁹⁶ In a prospective randomized trial of 32 children with ependymomas treated with either 8-drugs-in-1-day therapy before and after radiotherapy or with radiotherapy plus adjuvant CCNU and VCR chemotherapy, the 5-year PFS rate was 50% ± 10%, and the type of chemotherapy employed did not affect outcome.¹⁹⁷ A single-arm study using hyperfractionated radiation therapy followed by carboplatin, VCR, ifosfamide, and etoposide chemotherapy suggested an early impressive degree

of disease control, but long-term follow-up has not been reported.¹⁹⁸

The outcome of children with ependymomas seems to depend most on the extent of resection at the time of diagnosis. Patients with totally resected tumors have been reported to have survival rates as high as 70% 5 years after diagnosis. Chemotherapy trials are thus also aimed at seeing whether second-look surgery may be rendered feasible. There appears to be no clear effect of tumor location or histologic grade on outcome in patients with totally resected tumors, although more recent studies suggest that anaplasia may confer a worse prognosis and that completely resected nonanaplastic supratentorial ependymomas may be observed.¹⁹⁹ For this reason, the majority of adjuvant chemotherapy trials are now focusing on patients with subtotally resected tumors or those who have leptomeningeal spread at the time of diagnosis. A CCG trial using preradiation cyclophosphamide, VCR, cisplatin, and etoposide in 37 patients demonstrated an objective response rate of more than 50% and a 3-year EFS rate of 55% ± 9%.²⁰⁰ Preradiation chemotherapeutic studies and postradiation chemotherapy for those with residual tumor are being performed in an attempt to see whether chemotherapy-induced “complete resection” can improve survival, as well as to identify active drug regimens. Most recently, high-throughput methods of screening Food and Drug Administration (FDA)-approved compounds in both *in vitro* and *in vivo* models of ependymoma have yielded possible drug candidates, including 5-fluorouracil.²⁰¹

50.5.8 Germ Cell Tumors

Chemotherapy is an integral component of the treatment of testicular and ovarian germ cell tumors, but it has not been routinely integrated into the management of intracranial germ cell tumors.^{202,203} Because localized germinomas have high response and cure rates after radiation therapy alone, there has been limited experience with chemotherapy used either as an adjuvant after radiotherapy or alone after surgery for patients with newly diagnosed nondisseminated germinomas. Chemotherapy has been used more widely for patients with disseminated germinomas at the time of diagnosis and for the occasional patient who has failed initial surgery and radiation.²⁰⁴ Recently, there have also been attempts to use chemotherapy before radiotherapy in patients with localized disease to allow a reduction in the amount and volume of radiotherapy required for disease control.^{205,206}

The outcome of patients with intracranial nongerminomatous germ cell tumors is quite poor, with most series reporting survival rates of considerably less than 50% at 5 years. These patients have occasionally been treated with chemotherapy, although large groups of similarly treated patients do not exist.

Response has been demonstrated for a variety of individual drugs and drug regimens in patients with germinomas. These drugs include high-dose cyclophosphamide, methotrexate, CPDD, and regimens using the same drugs together with other agents, such as BCNU, procarbazine, bleomycin, VP-16, vinblastine, and actinomycin D.^{204,207} In one series, CPDD was demonstrated to result in rapid tumor shrinkage in 4 of 8 patients with germinomas and teratomas.²⁰⁸ Cyclophosphamide alone or in combination with vinblastine, bleomycin, cyclophosphamide, and CPDD resulted in a complete response in 10 of 11 patients

with newly diagnosed germinomas, including 7 who had disseminated disease at the time of diagnosis.²⁰⁶ The remaining patient had a partial response to treatment. In this study, the dose of radiotherapy to the primary site was reduced from 5,500 to 3,000 cGy, and the craniospinal dose was lowered from 3,600 to 2,000 cGy; 10 of the 11 patients were disease-free at a median follow-up of 47 months. All 4 patients with nongerminomatous germ cell tumors in this series were treated with the multidrug regimen and full-dose craniospinal radiation therapy, but recurrent disease ultimately developed. In a smaller series, carboplatin as a single agent resulted in a high response rate in patients with both localized and disseminated germinomas.

As an outgrowth of these studies, attempts have been made to use chemotherapy alone in children and adults with primary intracranial germ cell tumors. In the largest series to date, 71 children and adults with either germinomas or nongerminomatous germ cell tumors were treated with postsurgery cycles of carboplatin, etoposide, and bleomycin.²⁰⁹ Of 68 patients, 39 had a complete response after four cycles of chemotherapy, 24 had a partial response, 4 had stable disease, and 4 had progressive disease. Of the 29 patients in this series who had less than a complete response after four cycles of therapy, 16 were re-treated with the same three-drug regimen plus high-dose cyclophosphamide. A complete response was ultimately achieved in 10 of these 16 patients. Interestingly, the frequency of response did not differ between the patients with germinomas and those with nongerminomatous germ cell tumors. Tumor recurrence developed in 55% of the patients in this series at a median of 18 months from diagnosis, and there was no clear difference between the patients with germinomas and those with nongerminomatous germ cell tumors. Of the 45 patients with germinomas entered on the protocol, 22 developed tumor progression and 4 died of treatment-related complications. Overall, this PFS rate after chemotherapy alone seems significantly poorer than what has been reported in other series treating patients with radiation therapy alone; however, it is unclear how many patients in this series can be adequately salvaged (or possibly cured) by subsequent radiation therapy.²⁰⁹

Based on these results, it is difficult to make definitive recommendations concerning the use of chemotherapy for patients with intracranial germinomas and nongerminomatous germ cell tumors. Although the information available suggests that these tumors are chemosensitive, it is unclear whether the addition of chemotherapy to radiation results in better survival. There is some suggestion that chemotherapy will allow a reduction in the dose of radiation therapy, especially in those children with disseminated disease. Given the poor outcome of patients with nongerminomatous germ cell tumors, most investigators suggest that chemotherapy be used either before or following radiation therapy. However, the most effective regimen has not yet been determined and is being assessed by multiple investigations, including national studies (► Table 50.3).

50.5.9 Choroid Plexus Tumors

The management of choroid plexus papilloma is usually purely surgical, and there is no documented role for chemotherapy in this disease. The outcome of patients with choroid plexus carcinoma is less favorable, and chemotherapy has been employed both at the time of tumor recurrence and at the time of

diagnosis. At the time of tumor recurrence, responses can be documented to a variety of agents, including VP-16. For patients with newly diagnosed disease, the best reported outcome after the use of chemotherapy has been following the treatment of infants and young children with surgery and cyclophosphamide, VCR, VP-16, and cisplatin.²¹⁰ However, the majority of children who experienced prolonged disease remission after such treatment had total resections, and it is unclear whether chemotherapy increased the likelihood of disease control. In one study, the use of ifosfamide, carboplatin, and etoposide appeared to facilitate second-look surgery and avoid radiation, with 8 of 13 patients experiencing a median long-term survival of approximately 7 years.²¹¹

50.6 Chemotherapy and Infant Tumors

As outlined in previous sections, chemotherapy has recently been extensively used in infants with both malignant and benign tumors. The widest experience has been with the use of chemotherapy in young children with newly diagnosed medulloblastomas and other PNETs. In patients with such tumors who have residual disease after surgery, a variety of single-drug and multiple-drug regimens have been shown to shrink tumors, but fewer than one-half of patients attain a complete response after induction chemotherapy (independently of the type of regimen used).^{113,114,149–152,212,213} In patients with less than a complete response, tumors usually recur within months of diagnosis. At the time of tumor recurrence after chemotherapy, both radiation therapy and high-dose chemotherapy may once again induce remission. In one study, after initial chemotherapy failure, reinduction was successfully achieved with the use of higher-dose busulfan-based chemotherapy followed by some form of radiotherapy.⁹⁶ For patients with local failure, radiotherapy was delivered locally, and a high percentage of patients had prolonged disease control. In contrast, when failure was disseminated, treatment with high-dose chemotherapy followed by craniospinal radiotherapy was unsuccessful in controlling disease.

An effective regimen that will result in a higher than 50% complete response rate in patients with residual disease or disseminated disease at the time of diagnosis has not been identified. The most appropriate management for patients with a complete response after initial chemotherapy, or with no residual disease after surgery and a continued complete absence of tumor after induction chemotherapy, is unclear and controversial. Some investigators have recommended high-dose chemotherapy supplemented by either autologous bone marrow rescue or peripheral stem cell rescue as consolidation therapy.¹¹⁷ Others have recommended radiation therapy (either craniospinal or focused). Several groups have advocated the use of chemotherapy after initially incomplete resection of choroid plexus carcinomas as a way to diminish tumor bulk and vascularity, and (it is hoped) permit a second-stage complete resection. Maintenance chemotherapy is also being employed in patients without residual disease after surgery and induction treatment.

Surprisingly, some studies have suggested that infants with malignant gliomas fare as well as, if not better than, infants

with medulloblastomas after treatment with chemotherapy alone. The numbers of patients treated with chemotherapy alone (and therefore the number of studies) are quite small, but response rates as high as 60% have been reported. It has been postulated, but not proved, that infants with malignant gliomas may harbor tumors that are biologically different from those of older children and adults with histologically similar lesions.

The treatment of infants with ependymomas remains quite problematic. In one series, the regimen of cyclophosphamide, VCR, CPDD, and VP-16 resulted in transient tumor control in nearly 50% of infants with ependymoma. In this study, radiation was given after the completion of chemotherapy.²¹⁴ Attempts to use high-dose chemotherapy with agents like thiotepa, carboplatin, VP-16, and busulfan have not been effective in the setting of recurrence or in patients with newly diagnosed disease.

The outcomes of infants with several rare malignant primary CNS tumors, such as atypical teratoid/rhabdoid tumors (AT/RTs) and medulloepitheliomas, are quite poor, and the infants rarely survive. Although a variety of chemotherapeutic agents, some administered in high doses, have been used for children with atypical teratoid tumors, no chemotherapeutic regimen alone has yet demonstrated a response rate of more than 10 to 20% or the ability to induce long-term disease control. Older children with AT/RT treated with craniospinal and local radiotherapy and adjuvant chemotherapy have an apparent survival rate of more than 50% at 3 years.²¹⁵

The treatment of infants with low-grade tumors, especially low-grade gliomas, has been extensively evaluated over the past two decades. Increasing information suggests that chemotherapy, as outlined in the section on low-grade gliomas, will at least delay the need for alternative means of treatment for years after the initial diagnosis. However, infants with low-grade gliomas have a shorter period of EFS than do those older than 2 or 3 years at the time of treatment.

50.7 Conclusion

Given the uncertainty surrounding the “best” treatment for childhood brain tumors, chemotherapy should usually be used as part of a prospective treatment trial.

Pearls

- Chemotherapy has a definite role in the treatment of newly diagnosed medulloblastoma.
- Chemotherapy may result in objective tumor shrinkage in childhood low-grade gliomas and delay the need for radiotherapy.
- Chemotherapy can delay and in some cases obviate the need for radiotherapy in infants and young children with malignant brain tumors, primarily those with localized disease who have minimal residual disease after surgery.
- Chemotherapy is often a significant component of the multidisciplinary management of children with brain tumors.
- Molecularly targeted therapy is being actively explored in children with brain tumors, but these agents have not yet been incorporated effectively into treatment approaches.

51 Radiotherapy of Pediatric Brain Tumors

Thomas E. Merchant and Erin S. Murphy

During the past 20 years, the role of radiation therapy in the treatment of childhood brain tumors has increased owing to the promise of new treatment methods and an improved understanding of the indications, critical parameters, and side effects attributed to this modality. Future investigations will tailor the selective use, sequencing, and escalation and de-escalation of radiation dose and volume. Advancement beyond conformal and intensity-modulated radiation therapy is anticipated with the use of proton therapy. The latter has been used only in its earliest form (passively scattered or three-dimensional conformal proton therapy) and will soon give way to the preferred method of spot scanning, which will allow intensity-modulated proton therapy.

51.1 Medulloblastoma

Medulloblastoma is the most common malignant brain tumor in children and presents at a median age of 5 to 7 years. The negative consequences of this tumor and the side effects of irradiation are offset only by the knowledge that radiation therapy has curative potential, in even the most advanced cases.

51.1.1 Prognostic Factors

Prognostic factors for medulloblastoma include the extent of disease and resection, age at presentation, and the intensity and quality of radiation therapy and chemotherapy. The effect of age at presentation is highly correlated with the selection of treatment and the delay or omission of radiation therapy in the front-line management of the disease in very young children. More recently, histopathologic and molecular subtyping studies have identified small subgroups for which survival is excellent or very poor.¹⁻⁴ How the histopathologic and molecular grouping affects the use of radiation therapy remains to be determined.

51.1.2 Radiotherapy

Several decades ago, the standard of care for children with medulloblastoma included surgery and craniospinal irradiation; chemotherapy was experimental. Craniospinal irradiation included treatment of the neuraxis, including all subarachnoid volumes contiguous with the central nervous system (CNS) and cerebrospinal fluid (CSF) pathways, and supplemental ("boost") irradiation of the primary site. The neuraxis component of therapy received 36 Gy, and the boost volume, formerly the anatomical posterior fossa, received approximately 54 Gy.

Treatment of Standard-Risk Medulloblastoma

The use of craniospinal irradiation changed markedly when investigators explored reducing the craniospinal dose for patients characterized as having standard-risk disease (i.e., those without metastatic disease or substantial residual or extensive tumor). In 1999, the Children's Cancer Group CCG-9892 study

showed that the addition of postradiation chemotherapy (lomustine, vincristine, and cisplatin) to a reduced-dose (23.4 Gy) craniospinal irradiation regimen resulted in a 5-year progression free survival (PFS) of 79%; thus, the addition of chemotherapy to the treatment regimen permitted a 12.6-Gy reduction in the craniospinal dose without affecting the rate of tumor progression.⁵ Since then, little has changed therapeutically in terms of disease control. Indeed, the confirmatory A9961 study (conducted between 1996 and 2000 and reported in 2006) showed that a postradiation regimen of vincristine, cisplatin, and lomustine resulted in a 5-year event-free survival (EFS) rate of 82%; the combination of vincristine, cisplatin, and cyclophosphamide resulted in a rate of 80%.⁶ The latter regimen had a slightly higher rate of acute toxicity, and some concern remains about the high incidence of secondary tumors in this treatment group.

Complications

The classic portals for the boost volume included a pair of parallel opposed beams targeting the entire posterior fossa with margin. When this type of treatment was delivered to very young children, the loss of IQ was approximately 4.2 points per year, even at the reduced craniospinal dose of 23.4 Gy.⁷ Children who likely started out with a low-average IQ would be expected to have a subnormal IQ within 3 years after completing radiation therapy. With no plateau, intellectual disability would be expected by 5 to 6 years after treatment. It was concluded that unless the method of primary site irradiation (posterior fossa boost) was modified, very little could be done to change the volume receiving the highest (> 45 Gy) doses.

The first prospective trial to reduce the dose to the posterior fossa was conducted between 1996 and 2003 in children with standard-risk medulloblastoma, defined as T1 to T3B and M0 disease according to the Chang staging system.⁸ Postoperative residual disease measuring less than 1.5 cm² received craniospinal irradiation (23.4 Gy), conformal posterior fossa irradiation (36 Gy), and conformal primary site irradiation (55.8 Gy) with a 2-cm clinical target volume margin. Radiation therapy was followed by high-dose chemotherapy with peripheral blood stem cell support. Children treated with this regimen, which reduced the volume of the posterior fossa receiving the prescribed boost dose by almost 15%, had a 5-year EFS rate of 83.0% (standard deviation [SD], 5.3%), and no change was noted in the pattern of treatment failure. This modest reduction in the volume receiving the highest dose lowered IQ loss to only 2.4 points per year.⁹

Emerging data strengthen the association between the distribution of dose to regional volumes of normal brain and decline in cognitive function in several domains. The negative effect on IQ and academic test scores associated with increasing mean dose was shown for the entire brain volume, supratentorial brain volume, left and right temporal lobes, and left hippocampus (IQ, math and reading scores).¹⁰ Proton therapy is an excellent measure to reduce extra-CNS and CNS doses in these patients: photon dose volume data associated with a decline in IQ are graphically inferior to proton dose volume data for similar patients.¹¹

Another important and devastating side effect of radiation therapy is CNS necrosis. Among 148 patients who received 23.4 Gy of craniospinal irradiation and 88 patients who received more than 36 Gy of craniospinal irradiation, the cumulative incidence of CNS necrosis at 5 years was 3.7% (SD, 1.3%).¹² Those patients in whom CNS necrosis was observed had the largest infratentorial volumes, receiving doses in excess of 50, 52, and 54 Gy, providing new limits of tolerance for children with medulloblastoma and other CNS embryonal tumors treated with aggressive surgery, craniospinal irradiation, and intensive chemotherapy.

51.1.3 Treatment Alternatives

Biology is likely to have an effect on risk stratification in future trials. Because 30% of patients present with metastatic disease, extent of disease will remain an important factor. By histopathology, 10% of patients have desmoplastic medulloblastoma and a favorable prognosis, 74% have classic medulloblastoma and an intermediate prognosis, and 16% have anaplastic medulloblastoma and a poor prognosis. According to the biological subgroup classification, 13% of patients have Wnt pathway activation and an excellent prognosis, 17% have sonic hedgehog activation and a less favorable outcome, and the remaining 70% have biological tumor subtypes and a range of outcomes ranging from average to poor. Options for managing patients who have standard-risk disease with favorable clinical–pathologic and molecular risk features include omitting radiation therapy altogether, omitting craniospinal irradiation, and reducing the dose to the neuraxis and primary site. For patients with high-risk disease, considerations include intensifying the radiation dose and volume, administering chemotherapy and radiation therapy concurrently, and escalating the dose at the primary site if local treatment failure is the associated pattern of failure.

51.1.4 Medulloblastoma in Patients Younger than 3 Years

Some of the greatest recent changes in how medulloblastoma is treated have been in the youngest patients. More recent studies have used radiation therapy in the front-line management of these patients following an approximately 4-month-long induction phase of postoperative chemotherapy. The Pediatric Brain Tumor Consortium PBTC-001 study reported in 2005 used the standard four agents of cisplatin, vincristine, cyclophosphamide, and etoposide, in conjunction with intrathecal mafosfamide, followed by radiation therapy.¹³ Radiation therapy was risk-stratified on the basis of age and extent of disease and ranged from 45 Gy (cumulative primary site dose) for the younger and lowest-risk group (after gross total resection) to 54 Gy for the older patients and those with residual disease at the time of irradiation. The 5-year PFS rate exceeded 50% in the cohort of children in whom craniospinal irradiation was omitted.

In the Children's Oncology Group (COG) A9934 study, the use of similar systemic chemotherapy without intrathecal therapy and focal irradiation to 50.4–54 Gy resulted in a 4-year PFS rate of 50% (SD, 6%).¹⁴ PFS rates were improved by using a strategy of initial surgery; induction chemotherapy for 4 months; second surgery when necessary; and age-, risk-, and response-adaptive conformal radiation therapy with posterior fossa treatment and

primary site irradiation, followed by 8 months of chemotherapy with conventional agents. The A9934 study included irradiation with a 10-mm clinical target volume margin. Patients whose disease progressed during induction chemotherapy experienced primary site treatment failure, whereas those with disease progression after radiation therapy experienced neuraxis failure in the spine or regions of the brain that were spared by the omission of craniospinal irradiation (► Fig. 51.1). The newer regimens that prescribe early but not immediate postoperative radiation therapy have a very high rate of local tumor control.

51.1.5 Reducing Radiation Dose and Volume

As outlined earlier, clinical–pathologic and molecular risk classification will help to stratify patients for treatment. Radiation dose and volume may be able to be reduced in some children with medulloblastoma. Strategies for achieving such reductions include reducing the craniospinal dose to 18 Gy, as was done in the COG ACNS0331 trial; reducing the cumulative dose to the primary site to 45–50 Gy, as was done in the PBTC-001 and A9934 trials; and reducing the clinical target volumes for the boost component of therapy. Other strategies to consider are partial irradiation of the tumor bed and radiation therapy methods that spare normal tissue, such as intensity-modulated photon therapy or one of the current or developing methods of proton therapy.

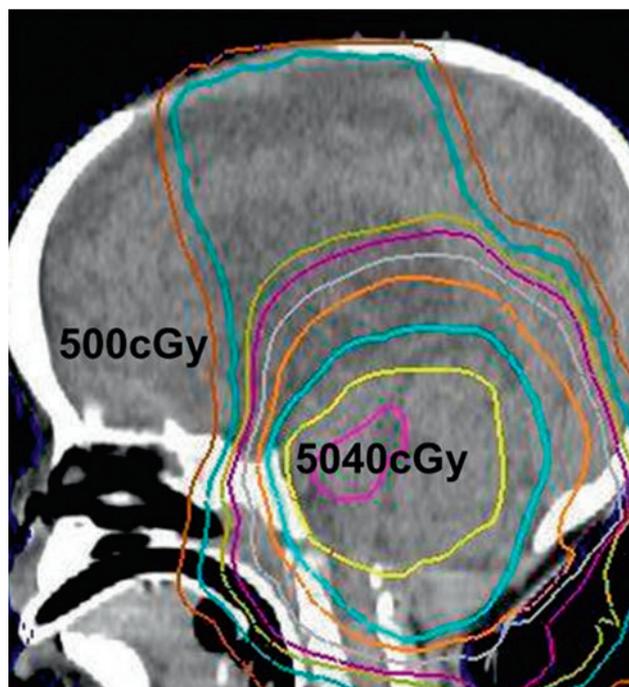

Fig. 51.1 Sagittal computed tomographic scan of a very young child (age younger than 3 years) with medulloblastoma treated in the Children's Oncology Group A9934 study by conformal radiation therapy (ca. 2000). Dose gradient from 5,040 to 500 cGy is apparent. Low-dose regions were the site of metastatic failure after radiation therapy.

51.2 Ependymoma

Ependymoma is the third most common brain tumor in children. The incidence is highest in very young children, which is relevant when the indications for radiation therapy are considered. In children, ependymoma most often arises in the infratentorial compartment and is intimately associated with neurovascular structures and the brainstem. This is important because of the normal tissue dose constraints that one must consider in planning radiation therapy. Supratentorial ependymoma may arise in the lining of the ventricular system or within brain parenchyma. In these cases, the postoperative tumor bed may range from a simple spherical structure to a large intracranial cavity, with associated subdural hygroma or complex or unidentifiable tumor volume.

51.2.1 Three-Dimensional Radiation Therapy

In 1993, the International Commission on Radiation Units and Measurements outlined a nomenclature for target volumes and three-dimensional radiation therapy planning. These recommendations were first adopted for the treatment of ependymoma in the St. Jude Children's Research Hospital RT1 trial. The gross tumor volume was defined as the residual tumor and/or the tumor bed; the clinical target volume was an expansion of the gross tumor volume, with an additional margin of 10 mm that was anatomically constrained at barriers where tumor invasion was unlikely (e.g., base of skull, calvaria, tentorium); and the planning target volume (PTV) was a margin meant to account for geometric uncertainty (3 to 5 mm). The trial included 153 patients treated between 1997 and 2007. The 7-year EFS and overall survival (OS) rates were 72% (SD, 6%) and 81% (SD, 5%), respectively. The 7-year local control rate was 83% (SD, 5%), the 7-year cumulative incidence of local failure was 16.3% (SD, 3.4%), and the 7-year cumulative incidence of distant metastasis was 11.5% (SD, 2.9%).¹⁵

51.2.2 Reducing Radiation Volume

The initial experience with three-dimensional planning for ependymoma included multiple beams at various orientations pointed at the planning target volume. Each beam had the beam's eye view shape of the planning target volume. The intersection of the beams results in a dose distribution that is adjusted and weighted to shape the prescribed dose (54 to 59.4 Gy) to the planning target volume. When treatment plans were initially developed with this early three-dimensional treatment-planning process, it was apparent that large volumes of normal brain could be spared in the process of treatment planning and delivery.

These methods were further refined to include intensity-modulated radiation therapy, a more sophisticated form of three-dimensional conformal radiation therapy in which computation-intensive iterative planning is used to balance dose constraints for normal tissues against target volume coverage goals. The prospect of sparing normal tissues in a young and vulnerable patient population accelerated referrals for systematic conformal radiation therapy in the late 1990s and likely led to the more aggressive preradiation optimization of patients to minimize the amount of residual disease before irradiation. A targeting example for ACNS0831, the current COG trial, appears in ► Fig. 51.2.

51.2.3 Complications

Cognitive outcomes were reported along with disease control for the patients with ependymoma in the St. Jude Children's Research Hospital RT1 trial.¹⁶ No decline in IQ was noted for the entire group, including the cohort of younger children (age younger than 3 years). The latter group had lower baseline values and no decline with time. With additional follow-up, now extending to more than 10 years, evidence that conformal radiation therapy spares cognition remains apparent. As an example, no clinically significant declines occur in the academic achievement of children with ependymoma treated with conformal radiation therapy.¹⁷ Similarly, verbal and visual auditory learning¹⁸ and adaptive behavior¹⁹ appear to be spared in children with ependymoma treated with focal conformal radiation therapy.

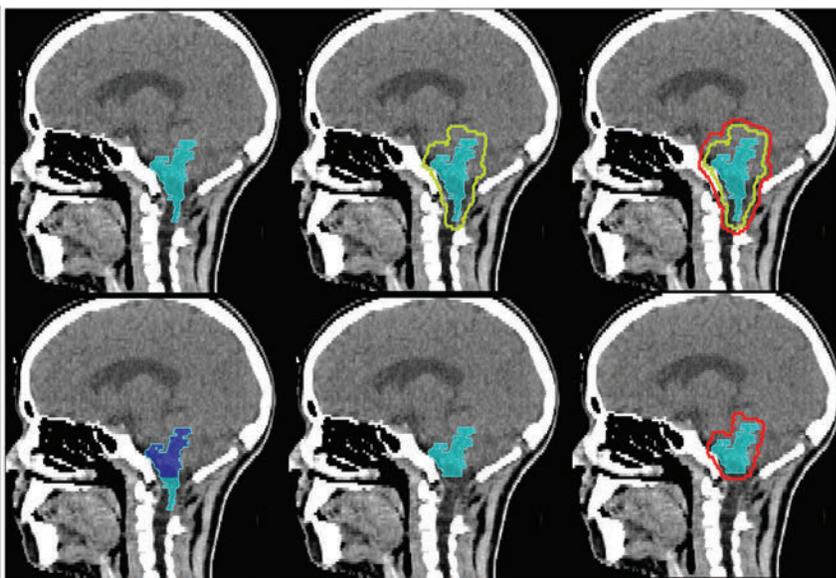

Fig. 51.2 Sagittal computed tomographic scans of a child with infratentorial ependymoma after gross total resection targeted for radiation therapy according to the ACNS0831 Children's Oncology Group guidelines. The postoperative tumor bed defines the gross tumor volume (upper, left), surrounded by a 5-mm anatomically constrained clinical target volume margin (upper, center) and a geometrically expanded 3-mm planning target volume margin (upper, right) targeted to receive 5,400 cGy. The second phase of treatment, an additional 540 cGy, targets the gross tumor volume, excluding the portion that is adjacent to the upper cervical spinal cord (lower, left and center). The modified gross tumor volume is geometrically expanded by 3 mm to create a second planning target volume (lower, right).

One of the added benefits of conformal radiation therapy is the ability to associate more precise estimates of radiation dose with functional outcomes. The dose to the hypothalamus has been directly correlated with the incidence and time to onset of clinically significant endocrine deficiencies in children with ependymoma and other brain tumors. Growth hormone secretion is the most common endocrine deficiency and the most sensitive to radiation dose.

Neurologic effects of irradiation on motor and sensory function and coordination are rare and are most often associated with infrequent cases of radiation necrosis. However, the effect of irradiation on recovery from tumor-related and surgery-acquired deficits should be considered, especially in children with infratentorial ependymoma after surgery for locally extensive disease. Prospective data suggest that the radiation dose does not impede recovery of neurologic function in children with ependymoma.

One additional aspect of neurologic function to consider is hearing loss after radiation therapy. Hearing loss as a function of time after radiation therapy is relatively uncommon, especially when the total dose to the cochlea can be limited to 45 Gy.²⁰ Thus, preservation of hearing is largely achievable in most patients when the target volume margins and parameters of some of the aforementioned clinical trials are used. With smaller clinical target volume margins, more precise methods of localization and verification, and intensity-modulated radiation therapy or proton therapy, irradiation of the cochlea with doses that will result in hearing loss should be infrequent unless the internal auditory canal is part of the intracranial volume at risk.

51.3 Low-Grade Glioma

Low-grade gliomas make up approximately 26% of childhood CNS malignancies seen in the United States.²¹ Low-grade gliomas are a heterogeneous group of tumors that are located most commonly in the cerebellum, followed by the cerebral hemispheres, the deep midline structures, the visual pathways, and the brainstem. Observation after gross total resection is the standard of care and can produce PFS rates of 80% for grade II tumors and more than 90% for grade I tumors.²² Tumors may demonstrate an indolent natural history after incomplete resection, but the PFS rate at 5 years is only 55%.²³ Therefore, neurologic symptoms, progression on imaging, or risk for progression at a critical site necessitates treatment with either radiation or chemotherapy. The choice of treatment remains controversial, particularly for younger children.

51.3.1 Treatment Alternatives

The sequencing of therapy is affected by physician bias, patient age, tumor location and grade, risks associated with progression, severity of symptoms, and lack of randomized evidence. Some studies show that immediate adjuvant radiotherapy improves PFS rates,^{24–26} and one study suggests that such treatment improves seizure control.²⁴ Adjuvant radiotherapy after incomplete surgical resection increases the 10-year PFS rate from 40 to 82%.²⁶ More controversial is the benefit of immediate radiotherapy on survival in this setting, with only one study showing that immediate radiotherapy offers a survival benefit.²⁷ A trend toward survival benefit for radiotherapy has

also been shown for World Health Organization (WHO) grade II tumors.²⁸ However, the majority of studies demonstrate no survival advantage with the addition of radiotherapy.^{24,26,29,30} Therefore, after an incomplete resection, a course of observation is usually recommended for asymptomatic patients who are not at severe risk for neurologic compromise if the tumor progresses. The addition of radiotherapy to chemotherapy has demonstrated a PFS benefit over chemotherapy alone³¹; however, the ideal timing and sequence of radiotherapy and chemotherapy remain unknown.

51.3.2 Three-Dimensional Conformal Radiotherapy

Radiotherapy techniques have improved over time. A Phase II trial of three-dimensional conformal radiotherapy resulted in excellent 10-year EFS and OS rates of 74% and 96%, respectively.³² The tumor volumes were based on magnetic resonance images, and a 1-cm clinical target volume margin was used. Among 78 patients, 13 developed treatment failure: 4 with metastatic progression, 1 with marginal failure, and 8 with in-field failure. All patients were prospectively evaluated to determine the effect of conformal radiotherapy on cognitive abilities, hearing, and endocrinopathies.³³ It is important to note that patients with more aggressive surgery up front or with neurofibromatosis type 1 and younger children had lower baseline neurocognitive function before radiotherapy. Also, 24% of tested patients had growth hormone abnormalities before the initiation of radiotherapy. Cognitive effects 5 years after conformal radiotherapy correlated with patient age, neurofibromatosis type 1 status, tumor location and volume, extent of resection, and radiation dose. The effect of age exceeded that of radiation dose, and patients younger than 5 years experienced the greatest decline in cognition.

51.4 Optic Pathway Tumors

Radiation therapy is highly effective for optic pathway tumors, with 10-year PFS rates higher than 80%.^{34–37} The initial choice of therapy does not affect survival, but when radiotherapy is administered, PFS rates at both 5 and 10 years are improved.^{22,34,38} Many patients with optic pathway tumors present at a young age, with 25% younger than 18 months and 50% younger than 5 years.^{39,40} For children younger than 2 years, younger age and diencephalic syndrome are poor prognostic factors.⁴¹ After combination chemotherapy, progression has been noted at a median of 3 years from treatment.⁴² At the time of progression, second-line chemotherapy, surgical resection, and radiation therapy need to be considered, with a decision made by a multidisciplinary team. Data suggest that patients who undergo surgery before radiation therapy enter treatment with better visual acuity and have better long-term outcomes⁴³ (► Fig. 51.3).

51.5 World Health Organization Grade I Tumors

WHO grade I astrocytomas include juvenile pilocytic astrocytoma and subependymal giant cell astrocytoma and are generally characterized by well-circumscribed lesions.⁴⁴ Juvenile pilocytic astrocytomas are most commonly in the cerebellum

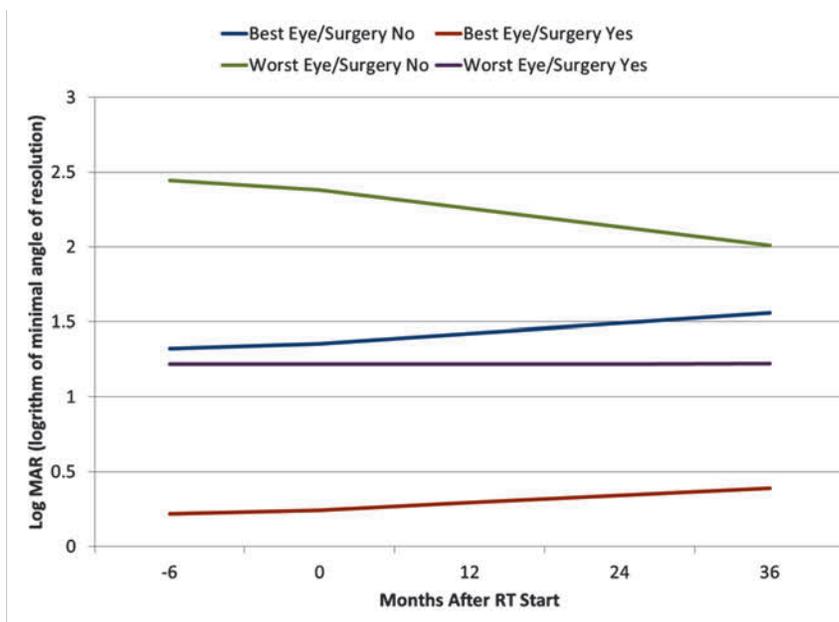

Fig. 51.3 Visual acuity before and after radiation therapy based on eye condition and surgical intervention. Log MAR 0 = 20/20; log MAR 1 = 20/200. Log MAR, logarithm of minimal angle of resolution. (Source: Awdeh RM, Kiehna EN, Drewry RD, et al. Visual outcomes in pediatric optic pathway glioma after conformal radiation therapy. *Int J Radiat Oncol Biol Phys* 2012;84 (1):46–51.⁴³)

and the diencephalic region; only 3% of patients have disseminated disease. Subependymal giant cell astrocytomas develop along the lining of the ventricles and are associated with tuberous sclerosis.

The primary treatment for WHO grade I tumors is maximal safe resection. The 15-year survival rate for completely resected tumors is 90%.⁴⁵ Radiation is recommended for symptomatic or progressive disease that cannot be resected or for residual disease with the potential to grow and damage critical structures.

Infratentorial tumors are more likely to be resectable,³⁵ whereas tumors in the deep tissues of the brain are less likely to be completely resected; therefore, they are likely to benefit from radiotherapy.⁴⁵ Children with deep-seated tumors treated with surgery and radiotherapy have a 15-year survival rate of 64%.⁴⁵ The recently changed WHO criteria now classify ganglioglioma as a WHO grade I tumor. These tumors do not respond as well to irradiation or chemotherapy as their pilocytic counterparts do.

51.6 World Health Organization Grade II Tumors

WHO grade II gliomas include diffuse astrocytoma, pleomorphic xanthoastrocytoma, oligodendroglioma, oligoastrocytoma, and pilomyxoid astrocytoma.⁴⁴ These tumors are more likely to progress than are WHO grade I tumors. A report of 90 children with WHO grade II glioma describes 5-year OS and PFS rates of 90% and 56%, respectively, with 10-year rates of 81% and 42%, respectively.³⁹ Of note, for patients older than 3 years without a gross total resection, the early administration of radiation does not appear to influence PFS or OS rates: the 10-year PFS rate is 43% whether the patients receive radiotherapy early or at the time of progression. A 15-year cumulative incidence of malignant transformation of 6.7% has been reported from a group of patients with low-grade (grade II) gliomas and did not correlate with the use of radiotherapy.⁴⁶

51.7 High-Grade Glioma

High-grade gliomas, including anaplastic astrocytoma (WHO grade III), anaplastic oligodendroglioma (WHO grade III), and glioblastoma multiforme (WHO grade IV), comprise 10 to 20% of pediatric brain tumors. These tumors are most commonly found in the cerebral hemispheres, thalamus, or basal ganglia. The molecular profile of childhood high-grade glioma is different from that of adult high-grade glioma and more often resembles that of a secondary glioblastoma multiforme, with an abundance of *TP53* mutations. Standard treatment for these aggressive tumors includes maximum safe resection followed by radiotherapy and chemotherapy, given either concurrently or sequentially. Gross total resection (i.e., >90% tumor resection) confers a clear PFS benefit.^{47–49} The most recent clinical trial reported 3-year EFS and OS rates of 11% ± 3% and 22% ± 5%, respectively, for a treatment regimen that included the administration of temozolomide concurrently with and after irradiation.⁵⁰ These results were inferior to those from a prior series⁴⁷ that included radiation therapy followed by multiagent chemotherapy. The respective 3-year and 5-year OS rates are 35% and 36% when children receive multimodality therapy.^{47,51} However, patients in a Phase II trial did not benefit from high-dose chemotherapy given before radiotherapy.⁵¹

51.8 Brainstem Glioma

The term *brainstem glioma* refers to both focal (20%) and diffuse intrinsic (80%) tumors.⁵² Patients with diffuse intrinsic tumors typically have a dismal prognosis, with a median OS of no more than 12 months.^{52–57} A short duration of presenting symptoms correlates with a worse survival.^{58,59} Attempts to improve outcomes have included hyperfractionated radiotherapy with total doses ranging from 66 to 78 Gy, resulting in median survival times of 8 to 13 months.^{60–67} A French trial reported improved survival of 17 months when front-line chemotherapy was used

before radiotherapy; however, the chemotherapy caused significant infections and increased hospitalization.⁶⁸ Concurrent chemotherapy has not demonstrated a benefit,^{63,69,70} nor have other strategies, including selective blood-brain barrier disruptors combined with chemotherapy,⁷¹ concurrent inhaled carbogen,⁵⁴ intravenous recombinant interferon- β ,⁷² and adjuvant chemotherapy.⁷³

51.9 Germ Cell Tumors

Pure germinomas, nongerminomatous germ cell tumor (NGGCT) subtypes (i.e., embryonal carcinoma, endodermal sinus tumor, choriocarcinoma), and teratomas comprise up to 70%, 20%, and 20% of all germ cell tumors, respectively. Together, these tumors account for approximately 4% of pediatric CNS neoplasms.^{32,74} They typically arise in the midline of the third ventricle, most commonly posteriorly in the pineal region, or by the anterior recess of the third ventricle.⁷⁵

51.9.1 Treatment Alternatives

Treatment for germ cell tumors continues to evolve over time and is based on the tumor type. Before safe biopsy of these tumors became available, radiotherapy was used as a diagnostic tool. If a tumor demonstrated a quick response to a radiation dose of 20 Gy, then it was classified as a germinoma.^{76,77} Now, stereotactic biopsy is often used to obtain a diagnosis and has a reported mortality rate of 1.3% and a neurologic morbidity rate of 3%.⁷⁸ Radical resection offers no benefit over biopsy alone for intracranial germinoma.⁷⁹ However, there is a benefit to surgical resection for NGGCT, in the form of both more accurate diagnosis⁷⁴ and better overall outcomes,⁸⁰ when it is combined with chemotherapy and radiation.

Radiation therapy is curative for pure germinoma, with reports documenting 10-year cause-specific survival and OS rates of up to 100% and 83%, respectively, for pathologically verified germinoma.^{77,81,82} A single-institution experience demonstrated 5-year rates of spinal axis failure and intracranial failure of 49% and 45%, respectively, for patients treated with partial-brain radiotherapy, compared with rates of 0% and 6% for those receiving whole-brain radiotherapy or craniospinal irradiation.⁸² The addition of chemotherapy has allowed volume and radiation dose to be reduced with equally good results.^{83–85} Prospective trials from the Société Internationale d'Oncologie Pédiatrique (French Society of Pediatric Oncology) and the Japanese Study Group show that relapses occur within the ventricles when involved-field radiotherapy (IFRT) is used after chemotherapy and have now changed their radiotherapy target to whole-ventricle irradiation (WVI) following chemotherapy.^{86–88}

Survival rates of patients with NGGCTs treated with chemotherapy followed by craniospinal irradiation with a boost to the primary site range from 67 to 74%.^{80,89} A Phase II COG trial for NGGCTs (ACNS0122) investigated neoadjuvant chemotherapy followed by 36 Gy of craniospinal irradiation and a boost to the primary tumor site or resection cavity for a total dose of 54 Gy. The patients who experienced a complete or partial response at the end of induction or who had mature teratoma or fibrosis at the time of second-look surgery had excellent 3-year EFS rates

ranging from 85.7 to 94.1%.⁹⁰ Therefore, ACNS1123 is investigating the role of reduced-volume radiotherapy (30.6 Gy of WVI and 54 Gy of IFRT) for patients with a good prognosis. The Japanese Study Group has reported outcomes of the treatment of patients with an intermediate prognosis with five cycles of carboplatin and etoposide, followed by WVI to 30.6 Gy and IFRT to 50 Gy, with 10-year PFS and OS rates of 81.5% and 89.3%, respectively.⁸⁸

51.10 Craniopharyngioma

Although craniopharyngioma in children is a histologically benign tumor, management with surgery and radiotherapy may be associated with varying morbidity. Complications include neurologic deficits, panhypopituitarism, diabetes insipidus, cognitive deficiencies, behavioral problems, visual disturbances, vasculopathy, malignant transformation, and secondary malignancies.^{91–97} Great care should be taken when therapeutic decisions are made for these children.

Craniopharyngioma can be managed with a gross total resection alone; however, even when gross total resection is confirmed by neuroimaging, the rate of recurrence is from 20 to 27%.^{98,99} Recurrence after surgery is related to tumor size, residual calcifications detected by computed tomography, and history of prior surgery or irradiation.^{98,99} The alternative to radical surgery is limited surgery and focal irradiation. The St. Jude Children's Research Hospital experience suggests that fewer complications occur after a combined-modality approach and a minimal extent of surgery have been used.¹⁰⁰ Ten-year PFS rates from 84 to 100% have been reported when patients undergo limited surgical resection followed by radiotherapy.^{101–103} In pediatric patients with craniopharyngioma, several factors are significantly associated with worse neurocognitive outcomes: age younger than 7.4 years, more extensive surgery, multiple surgical procedures, diabetes insipidus, hydrocephalus, CSF shunt, shunt revisions, Ommaya reservoir laterality, and cyst aspirations.¹⁰⁴ IQ is also affected by radiation dosimetry factors, including percent volume of total brain, supratentorial brain, and left temporal lobe receiving doses greater than 45 Gy.

Radiation oncologists should be aware that tumor cyst expansion during treatment is common and that serial magnetic resonance imaging should be performed, with consideration given to developing a new plan when there is a risk for target volume compromise.¹⁰⁵ Similarly, consideration may be given to cyst aspiration or decompression during radiotherapy without delaying radiation treatments. ▶ Fig. 51.4 displays modeled IQ data after surgery and radiation therapy for craniopharyngioma, with the effects of age and diabetes insipidus (a marker of the extent of surgery) shown.

Stereotactic radiosurgery may be appropriate for patients with craniopharyngioma who have recurrent disease after prior fractionated radiotherapy or residual disease after surgical decompression. Important considerations for radiosurgery include tumor location, marginal tumor dose, dose tolerance of critical structures, and prior therapy.^{106–112} A single-institution report describes a 5-year local control rate of 68% for residual or recurrent craniopharyngioma treated with the standard marginal dose of 13 Gy.¹¹³

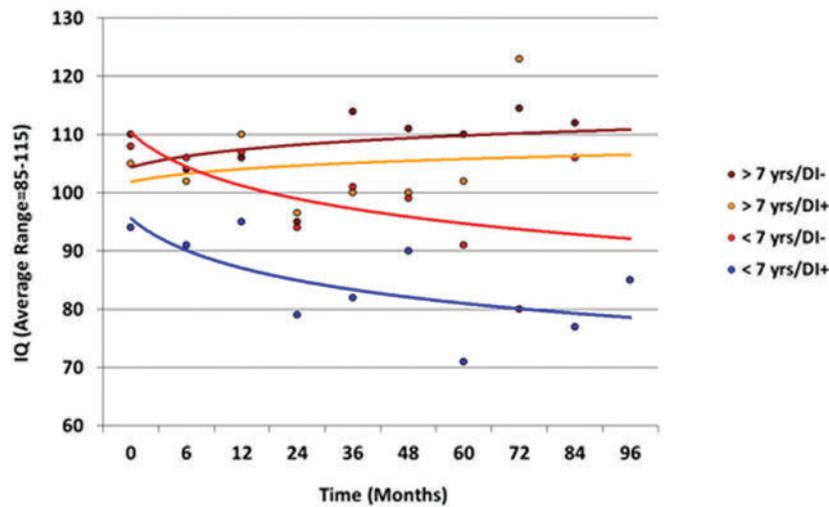

Fig. 51.4 IQ modeled as a function of time after irradiation, age, and diabetes insipidus. DI, diabetes insipidus.

Pearls

Patient Selection

- Radiation therapy is a component of front-line therapy in the management of nearly all childhood brain tumors.
- Be aware of current guidelines for target volume definition and associated treatment margins to minimize radiation dose and volume.

Surgical Optimization

- A greater extent of resection is associated with improved outcome in children with medulloblastoma, ependymoma, and high-grade glioma.
- There is no association between extent of resection and outcome in children with low-grade glioma, pure germinoma, and craniopharyngioma.

Sequencing and Response Assessment

- The early use of irradiation in the primary or adjuvant setting is associated with higher rates of control for most tumors.
- Pseudoprogression early after radiation therapy is common for many tumor types and does not indicate treatment failure.

Acute and Late Effects of Irradiation

- The side effects of radiation therapy have been reduced through the implementation of newer treatment methods.
- Tumor (hydrocephalus) and surgery-related morbidity contribute to the side effects observed after radiation therapy.
- There is a strong association between age at the time of irradiation and cognitive effects.

52 Nonaccidental Head Injuries

Ann-Christine Duhaime

Few topics in pediatric neurosurgical practice engender so much controversy and elicit such strong opinions as does nonaccidental injury. It is an area that most surgeons wish they never had to encounter because it rarely involves surgery at all, and it often thrusts them into a medical and medicolegal maelstrom that many would prefer to avoid. Although neurosurgeons are practiced in making firm decisions with incomplete information on a daily basis, this arena is altogether different, and for many, it is both unfamiliar and uncomfortable territory. Yet because it is common, and because the opinion of the neurosurgeon often holds considerable weight, it is important to have an overall understanding of what is known and what is at present still unknown in this area. The purpose of this chapter is to provide a practical overview for the neurosurgeon called to manage a case in which the differential diagnosis includes inflicted injury.

52.1 History and Terminology

Because some of the confusion in the field of child abuse arises from semantics and terminology, it is useful to understand the background from which some of the labels used for various “syndromes” arose. That children might present with a complex of signs and symptoms resulting from mistreatment at the hands of their caretakers was widely recognized by the medical field only in the middle of the 20th century, although the French physician Ambroise Tardieu attempted to raise awareness of child maltreatment a century earlier.¹ What is challenging, and often handicapping, about the presentation of these particular patients is that the true history of illness is usually withheld. Thus, the clinician must rely on the recognition of patterns of findings to infer that injury has occurred, and that it may not be accidental in etiology.

C. Henry Kempe, a pediatrician and chairman of pediatrics at Children’s Hospital Colorado, Denver, and his colleagues pioneered in the recognition of abusive injury in the United States with their description of children who presented for a variety of reasons but had certain physical and behavioral characteristics in common, and whose symptoms and signs resulted from chronic physical abuse and neglect.² Their so-called “battered child syndrome” was the first widely promulgated clinical constellation to bring the problem of inflicted injury into the consciousness of general pediatrics.

Moving into the realm of even younger children, John Caffey, a pediatric radiologist at the Children’s Hospital of Pittsburgh, Pennsylvania, noticed the relationship between long-bone metaphyseal fractures, subdural hematomas, and retinal hemorrhages in infants. In the 1960s and early 1970s, the role of angular deceleration forces in the biomechanics of concussive head injury and subdural hematoma was being recognized in primate experiments and in some case reports of adult head injury.^{3–5} Another event that contributed to how this new syndrome was conceptualized involved a well-publicized case in England during the late 1940s and 1950s, in which a nursemaid confessed to apparently causing injury to a number of her charges by shaking them in order to burp them.⁶ Thus, it was surmised

that manual shaking could generate sufficient angular deceleration of the infant head to result in the subdural hemorrhages commonly seen in these infants, and that shaking was therefore the causative mechanism. Caffey coined the term *whiplash shaken infant syndrome* to denote this condition, which became known in common parlance as shaken baby syndrome.^{7,8} Central to Caffey’s concept was that shaking was widely perceived as a nonharmful and acceptable method of discipline for infants, and that caretakers were unwittingly causing highly damaging or fatal injuries to their children by this practice.⁶

The past two decades have seen increasing recognition that inflicted head injury can take many forms. Single acute neurologic events, acute or healing skeletal trauma, and chronic subdural hemorrhages alone or in combination, with or without retinal hemorrhages, bruising, or signs of physical neglect, may be seen. The common findings of apnea and hypoxia are suspected by many to contribute to the pathogenesis of the more severe end of the acute injury syndrome.⁹ Neuropathologic findings in the cervical spine have been recognized, and whether trauma in this region, caused by manual shaking or some other mechanism, contributes to the clinical picture is an area of ongoing investigation.^{10–12} However, because the vast majority of children with inflicted injury have subdural hematomas, hypoxia alone seems unlikely as a full explanation for all the findings. As in other branches of medicine, it has become clear that the relatively simple notions of mechanism and context initially proposed in the 1960s and 1970s provided a useful and practical starting point, but that much more work is needed before clinicians have available a full and generalizable understanding of these types of injuries. For this reason, many authors and child advocacy organizations have adopted terminology that does not imply a single mechanism of injury but instead is more general, if admittedly less riveting, than “shaken baby syndrome.”¹³

As a matter of definition, in this chapter the terms *inflicted injury*, *nonaccidental injury*, and *abusive head injury* are used interchangeably to refer to trauma resulting from the deliberate application of force to a child.

52.2 Epidemiology

Research in the epidemiology of inflicted trauma has been hampered by the same factors inherent in research into other aspects of this topic, including difficulties with ascertainment, inclusion criteria, and follow-up. Nonetheless, several population-based studies have been conducted, and these serve to estimate the incidence of inflicted neurotrauma. A prospective population-based study in Scotland found that “shaken impact syndrome” occurred with an annual incidence of 24.6 per 100,000 children younger than 1 year of age. Cases were more common in urban areas and during autumn and winter. The risk for sustaining an inflicted head injury by 1 year of age was found to be 1 in 4,065.¹⁴ At least 24% of children younger than 2 years of age admitted to the hospital for head injury have sustained nonaccidental trauma.¹⁵

Inflicted neurotrauma is a syndrome of young children, with a mean age younger than 1 year.¹⁶ In most studies, boys are slightly more at risk than girls, although some studies show equal incidence rates.

Risk factors for inflicted injury include young parents, low socioeconomic status, socially unstable households, single parents, prematurity of the infant, history of prior abuse to the caretaker, and psychiatric or substance abuse histories.^{17–21} Perpetrators in order of frequency include fathers (37%), boyfriends (20.5%), female babysitters (17.3%), and mothers (12.6%).²² In a significant percentage of cases, evidence of prior trauma is present or inferred, although single events are also common.^{23–25}

52.3 Clinical Presentation and History

The two most common histories given by caretakers when children present with nonaccidental head injury include a history of trivial blunt trauma and no history of trauma. When a history of trauma is obtained, it is most often one of a low-height fall, usually from a bed or other low surface.^{16,24,26–28} When children present without a history pointing to trauma, they are brought to attention because of specific symptoms or signs, including feeding difficulty or vomiting, lethargy, irritability, abnormal movements, seizures, apnea, and unresponsiveness. Occasionally, the diagnosis will be suspected on the basis of findings noted on routine physical examination, such as an enlarging head or unusual or patterned bruising. When no history of trauma is given and the symptoms are nonspecific, a diagnosis of inflicted injury often may be missed. In one study of 173 children with abusive head injury, it was ascertained that signs and symptoms of inflicted injury had been present, but the diagnosis missed, at prior presentations for medical care in nearly one-third of children.²³ The diagnosis was more likely to be missed in young, Caucasian children from intact families who did not present with respiratory compromise or seizures. In 4 of 54 missed cases, the later presentation resulted in a fatality, underscoring the importance of considering the diagnosis of inflicted injury even when symptoms are nonspecific and no history of trauma is provided. Other authors also have discerned racial differences in the evaluation obtained for children presenting for care with similar injuries, reinforcing the fact that ascertainment bias may contribute to missed injuries (or, conversely, to unnecessary testing).²⁹

The best and most helpful history is that obtained at the initial contact. The neurosurgeon should make it clear that the goal is to understand what happened to the child, in order to anticipate what kinds of injuries may have been incurred, to tailor evaluation and management, and to anticipate potential delayed complications. This is true for all head injuries, accidental or otherwise.

After the initial history is provided by the caretaker, specific questions need to be asked and answers obtained. Exactly what happened? At what time did it occur? Who was there? How high was the fall/drop/trajectory? What kind of surface did the baby hit, and with what part of the body? What position was the baby in? Who saw it? If the incident was unwitnessed, who heard it or arrived at the scene? What did the baby look like and do? For how long? What happened next? It may be helpful

to describe that what you are trying to create is a “mental video” of the events surrounding the injury. An exact description of the events is invaluable and is best obtained right away. If the person who witnessed the injury is not present, that person should be interviewed as soon as possible.

Because the vast majority of low-height falls in childhood are well tolerated and result in minimal injury, the finding of more serious injuries from this purported mechanism is one of the more common reasons why suspicion of inflicted injury is raised in emergency department and primary care clinicians. This diagnostic criterion falls under the concept of injuries “inconsistent with” or “inadequately explained by” the reported mechanism. However, exactly what mechanism causes what injuries at what age is incompletely understood, although some progress in this area has been made in recent decades (see later section on mechanisms and types of injury). Nonetheless, few clinicians called upon to evaluate potentially injured children are fully knowledgeable regarding the available data in this area. Hence, in practice, the criteria for considering inflicted injury vary among clinicians and hospitals. For example, despite ample evidence to the contrary,^{30–32} many clinicians still believe that the presence of a skull fracture in an infant is inconsistent with a low-height fall. Epidural hematomas can result from low-height falls in infants, and although they can be serious or even life-threatening, they are only rarely due to inflicted injury.³³ Even when similarities in injury types are accounted for, the frequency with which referrals for evaluation for possible nonaccidental injury are made has been shown to be influenced by a number of factors, including the presence of two parents, the insurance status of the patient, and the race of the infant.^{23,29}

Retinal hemorrhages are reported in 65 to 95% of children with inflicted head injury, may be unilateral or bilateral, and are best seen with the use of mydriatics.^{26,34–36} The exact biomechanics or other conditions necessary to cause retinal hemorrhages are at present not well understood; they can be associated with normal vaginal delivery, coagulopathy, hypertension, accidental trauma, subarachnoid hemorrhage, subdural hemorrhage, papilledema, and some other uncommon conditions, including certain genetic disorders and rare cases of resuscitation.^{37–46} When accidental trauma is minor or mild, retinal hemorrhages are usually sparse and may be unilateral.^{15,44,47} However, severe, bilateral retinal hemorrhages, especially if associated with retinal folds or detachments, are associated with major traumatic forces in accidental trauma or with nonaccidental injuries, and they have not been reported from low-height falls.^{42,48–52}

Although some medical conditions can mimic certain aspects of acute and chronic inflicted injury, generally these conditions can be identified with a complete history and physical examination, appropriate imaging studies, and sometimes other specific evaluations, such as laboratory tests.^{43,53–55} Of somewhat greater difficulty is the distinction between inflicted and accidental trauma, and this will be discussed in more detail below. However, although there may be some diagnostic uncertainties in the assessment of possible nonaccidental trauma, there is no illness or condition known besides inflicted injury that causes the combination of acute subdural hemorrhage, healing skeletal injuries, and severe bilateral retinal hemorrhages (particularly if retinal folds or detachments are seen). When a single severe traumatic event (i.e., one involving very high-magnitude forces)

has occurred, acute subdural hemorrhage, acute fractures, and severe bilateral retinal hemorrhages may occur, but this combination of findings has not been reported in association with low-height falls.

52.4 Diagnostic Imaging

Nearly all types of head injury have been reported in the context of inflicted mechanisms, but the most common is acute subdural hematoma.^{12,15,16,35,56} Often, the hemorrhages are thin but extensive collections over the surface of one or both cerebral hemispheres, as well as in the posterior interhemispheric fissure (► Fig. 52.1). In some children, the brain parenchyma appears normal. In other children, parenchymal hypodensities may be present initially or appear within the first 1 to 2 days after trauma and may range from focal and patchy to extensive.^{57–59} In the latter case, an entire hemisphere or both supratentorial compartments may be affected, the so-called “big black brain”⁶⁰ (► Fig. 52.2). This extensive hypodensity does not appear in all children with inflicted injury but is seen in a subset of those who are the most impaired at presentation. The pathophysiology of this phenomenon is incompletely understood, but it seems to be unique to infants and young children. Diffuse hypodensity is bilateral in two-thirds of cases and unilateral in one-third, with the latter constellation more common in older infants and young children. Unilateral cases often include an affected region in the contralateral medial frontal region due to subfalcine herniation (► Fig. 52.2). In such cases, the

hypodensity is usually present on the side of the greater subdural hemorrhage.^{36,58,59,61,62} The observation that one-third of children with this finding have the unilateral form also argues against a pathophysiology related solely to apnea/hypoxia.⁶² Children in whom unilateral or bilateral “big black brain” develops usually are unresponsive on admission and have a mortality of 67%. Survivors tend to be very young, probably because the ability of the calvaria to expand serves as some protection against brainstem compression and fatal herniation.⁶¹ Outcome in survivors of bilateral hypodensity is dismal, with children remaining blind, nonverbal, nonambulatory, and profoundly developmentally impaired, thus making the utility of aggressive acute intervention in such cases arguable.⁶³

Magnetic resonance (MR) imaging may be helpful in identifying small subdural hemorrhages and parenchymal contusions that may be inapparent on a computed tomographic (CT) scan. However, the early hope that subdural hemorrhages could be reliably dated by MR imaging has not been realized because the multicompartmental nature of the traumatized subdural and subarachnoid spaces makes hemorrhagic collections layer and mix in various ways that may influence their signal characteristics.^{64,65} Thus, the dating of hemorrhages is only approximate and is not generally accurate to within specific hours or days, as is sometimes needed in criminal investigation. Diffusion-weighted imaging and spectroscopy have been used to corroborate the degree of parenchymal injury seen on CT.^{66,67} One of the main practical values of MR imaging is that it distinguishes extra-axial cerebrospinal fluid collections from hemorrhagic

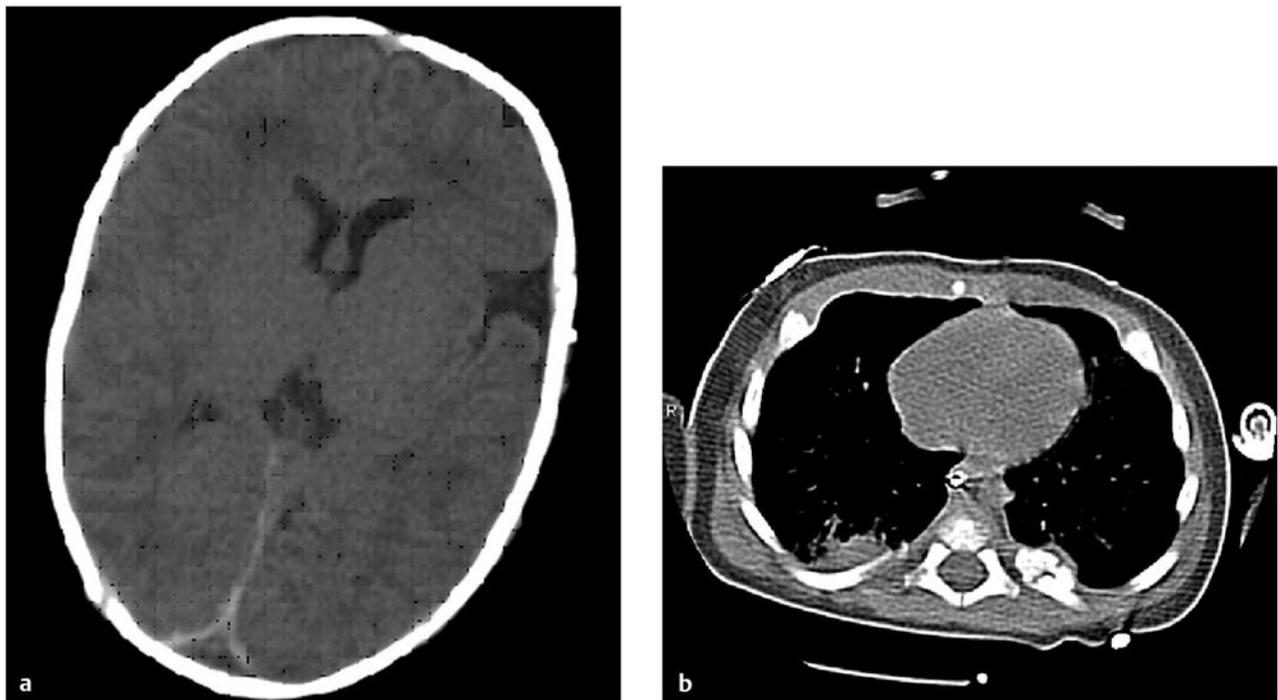

Fig. 52.1 Unenhanced computed tomographic (CT) scan of a 6-week-old baby who was found at home unresponsive with irregular breathing. There was no history of trauma. (a) Axial view through the brain showing interhemispheric blood. (b) CT scan of the chest showing a healing left posterior rib fracture.

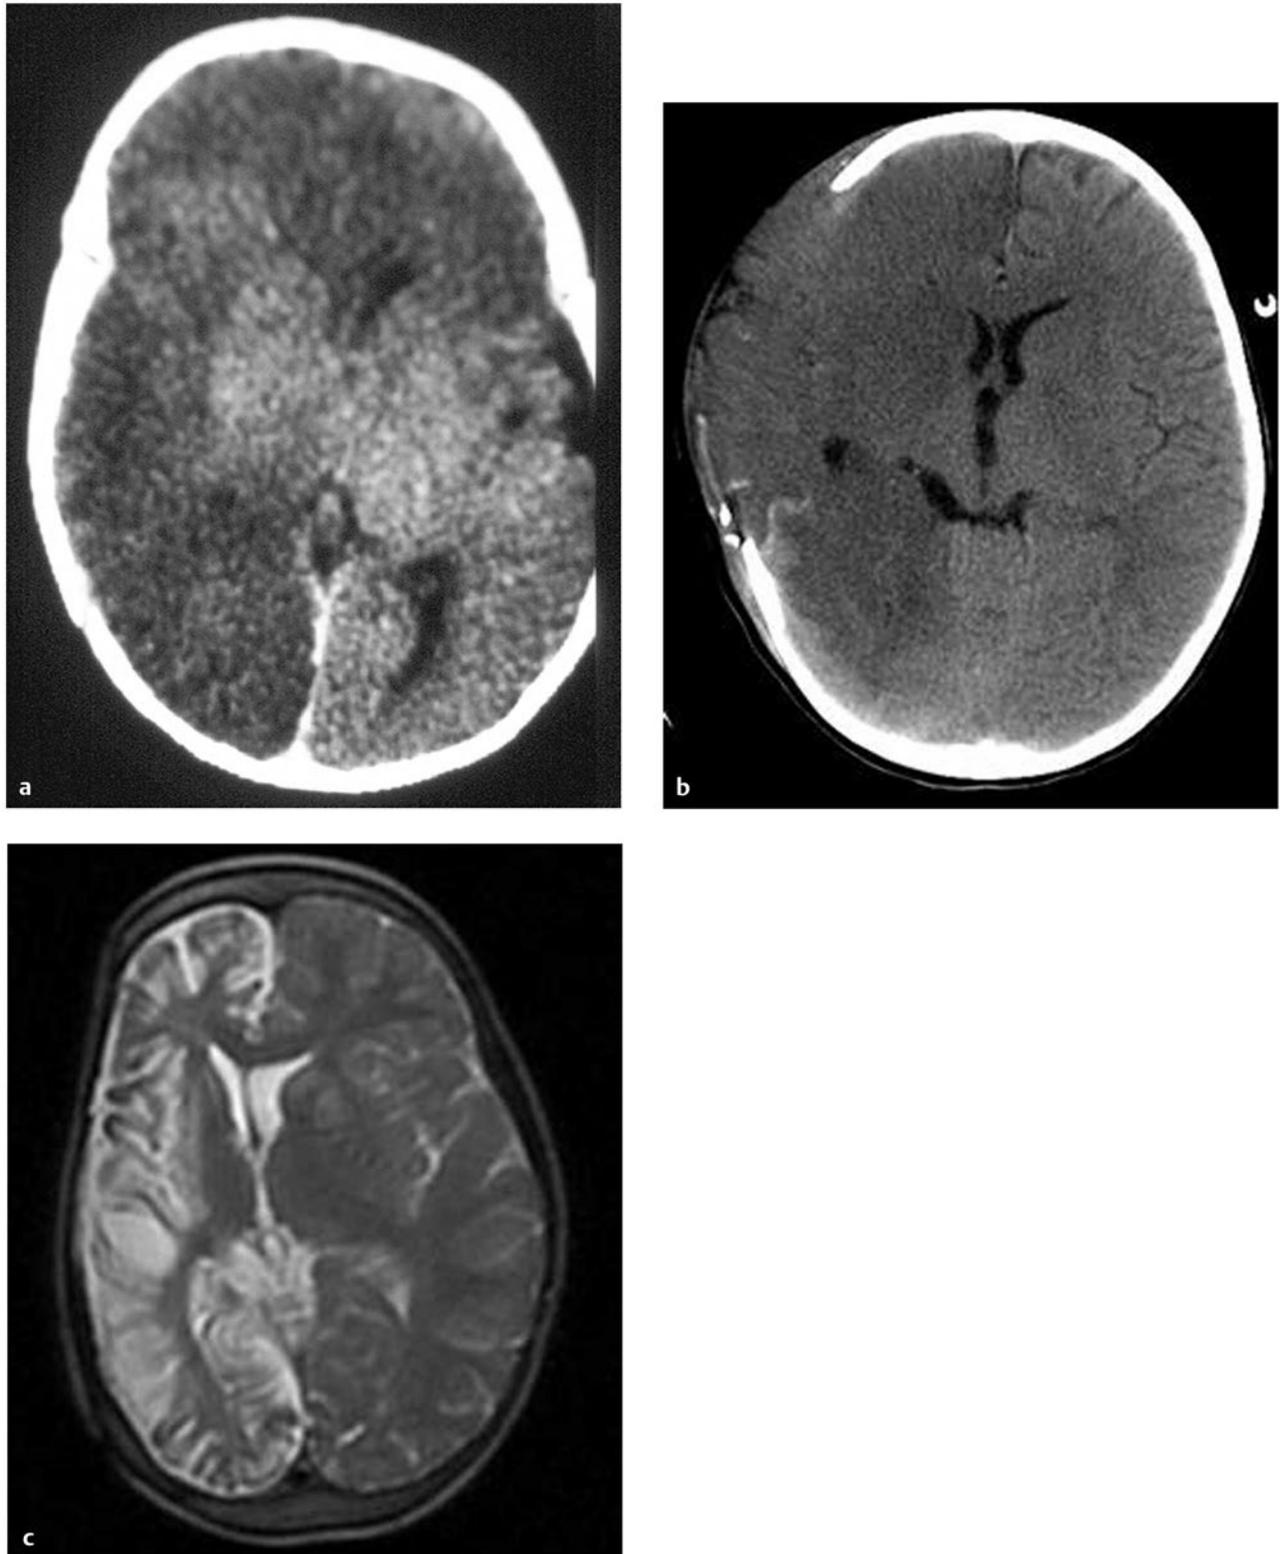

Fig. 52.2 (a) Unenhanced axial computed tomographic (CT) scan showing unilateral hypodensity of the entire hemisphere (“big black brain”) with involvement of the contralateral medial frontal lobe in a child with inflicted injury, likely reflecting subfalcine herniation. (b) CT scan in a child with inflicted injury treated acutely with cranial decompression. (c) Rapid T2 magnetic resonance image 2 years later. Note preservation of the contralateral frontal lobe.

subdural collections, which when identified point the clinician toward a consideration of a traumatic etiology for an enlarging head (► Fig. 52.3). In some children with macrocephaly as the presenting complaint, rapid MR imaging techniques, which do not require sedation (typically, fast-acquisition T2-weighted images in multiple planes), serve as an increasingly utilized means to differentiate chronic subdural collections from the much more common enlargement of the subarachnoid space⁶⁸ (► Fig. 52.4). Skull fractures are noted in approximately 25 to 75% of children, depending on the techniques used to assess them; historically, plain skull films are more likely to diagnose skull fractures than are CT scans, but in the digital era, the resolution of plain films may be decreased, and three-dimensional CT reconstructions with reduced radiation dosage may be the most reliable at present^{56,69–72} (► Fig. 52.5 and ► Fig. 52.6). Some fractures and scalp injuries are visible only at autopsy.^{12,24} Skeletal injuries to the ribs, long bones, or spine occur in 30 to 70% of children with inflicted head injuries.^{69,73} Fractures of the metaphyses of the long bones and to the posterior ribs are highly associated with inflicted mechanisms, and other injuries, such as spiral fractures of the femur, also occur with increased frequency in this setting. Because the identification of unexplained injuries is one of the most reliable adjuncts to a diagnosis of inflicted injury, a full skeletal survey should be performed, rather than a “babygram” (i.e., a single anteroposterior image of the entire infant) or other less thorough survey. Radioisotope bone scan also may be helpful in equivocal cases to identify subtle acute injury, and follow-up plain films can confirm the presence of healing bone injury.⁷⁴ Radioisotope bone scan may identify some skeletal injuries not seen on plain films and may be complementary.⁷⁵

Copy editor, note to Thieme: Caption for ► Fig. 52.7 has been moved to where the figure is first called out. Although evidence of injury to the cervical spine has been described with more consistency in several autopsy series, these injuries (which include extradural and intradural hemorrhages, nerve root injuries, and small parenchymal abnormalities) are rarely visualized on MR imaging.^{12,76–78}

Soft tissue injuries including frenulum tears and patterned bruising (e.g., loop marks, bite marks, or bruises in the pattern of a striking object) or burns may be seen.⁷⁹ Care should be taken to avoid misinterpreting the patterned bruises seen in some folk remedies practiced in various cultures, such as coin rubbing, as inflicted injury.

52.5 Mechanisms and Types of Injury in Infants and Young Children

Part of the confusion in the literature on injury in infants and children arises from semantics—that is, from terminology that is defined differently in different contexts or by different authors. Head injuries can be classified in a number of ways, including by injury type, by mechanism, and by severity. It is worth reviewing the terminology briefly because in the medicolegal context, these semantic differences can be problematic, and the unsuspecting physician acting as a fact or expert witness may find that these terms become a point of controversy during testimony.

First, head injuries may be classified by *pathoanatomical injury type*. This is the “where and what” of a specific injury. Thus, as is obvious to neurosurgeons, an epidural hematoma is located in the epidural space and is a clot, and scalp contusion, skull fracture, subdural hematoma, intracerebral hemorrhage, diffuse axonal injury, and other injury types also follow this “where and what” terminology. It is useful to keep in mind that many if not most clinical traumatic events produce more than one injury type.

Head injuries also may be classified by *mechanism*. These include impact and inertial events, the former requiring contact with the head and the latter reflecting movements of the head and/or brain. Inertial forces may be translational, in which the head moves in a straight line, or rotational (also described as angular), in which the head and/or brain moves around a center of rotation. The specific injuries incurred from a traumatic mechanism depend both on the *type* and the *magnitude* of the specific forces applied to the head and brain. In most clinical injuries, the head and brain are subjected to multiple types of forces at different magnitudes, even during a single event.^{80,81} For example, in a motor vehicle crash, the contact of the head with the dashboard results in focal contact forces at the site of impact, while the movement of the brain during deceleration results in the application of diffuse inertial forces throughout the brain parenchyma. A patient subjected to this mechanism may have both frontal brain contusions resulting from impact forces and diffuse axonal injury from inertial forces related to rapid angular deceleration.

Finally, head injuries may be classified by *severity*. The Glasgow Coma Scale (GCS) and its derivatives for the pediatric population have all been used to categorize acute injuries as mild, moderate, or severe. The original GCS was designed to be used at 6 hours after injury and after resuscitation to compare patients among different centers, and it was validated to be predictive of outcome after head injury in adults when used for that purpose.⁸² However, it has major drawbacks as a predictive tool in infants and preverbal children and is sensitive to influence by sedative and paralytic agents and intubation.⁸³ In addition, in common parlance, laypersons may think of a skull fracture as a “serious” injury, but from the neurologic point of view, a skull fracture may occur with essentially no injury to the brain and so is not “serious” in the sense of expected long-term consequences. Confusion over this sort of terminology can be vexing when neurosurgeons interact with legal or child protection professionals.

In the context of inflicted injury, these terms and classifications may arise with erroneous assumptions that are worth noting. For instance, with respect to pathoanatomical injury types, subdural hematomas are the most common intracranial hemorrhage in inflicted injuries in infancy, but there are different mechanisms that may be associated with subdural hemorrhages and different lesions that may be misinterpreted on CT scans as subdural hematomas.^{64,84} Thus, the presence of something that is or looks like a subdural hemorrhage does not in and of itself confirm a diagnosis of inflicted injury. Likewise, some nonaccidental injuries are “life-threatening,” but so are arterial epidural hematomas, which may arise from low-height falls in infants. Thus, the presence of a “serious” or “life-threatening” head injury does not by itself imply an inflicted mechanism, or even a mechanism that is necessarily inconsistent with

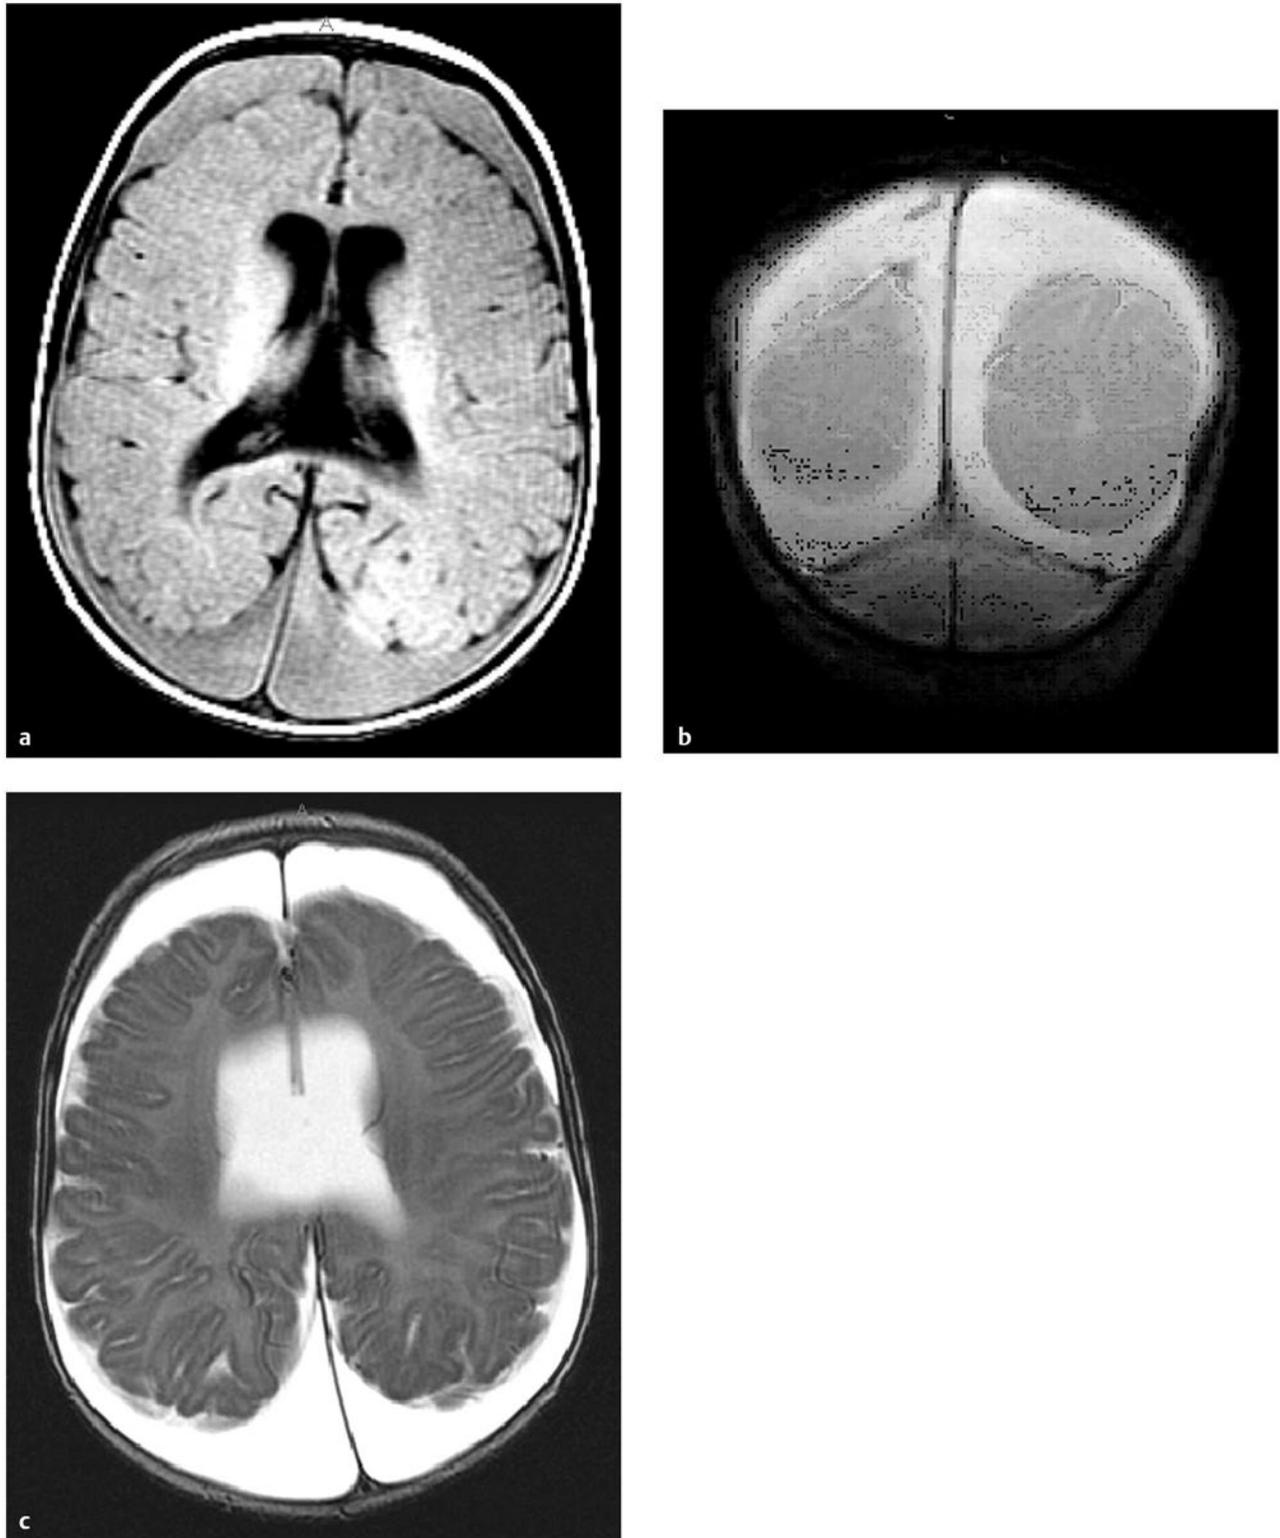

Fig. 52.3 Axial T1-weighted (a), coronal gradient-echo (b), and T2-weighted (c) magnetic resonance images of the brain of a 3-month-old infant with an enlarging head circumference. Note the ruptured parasagittal bridging vein in (b) and the tear in the septum pellucidum, best seen in (c). The infant was also found to have multiple healing fractures. The father, who had been abused as a child, admitted to throwing the infant on the floor and across the room when she cried.

the history given. Our colleagues in the legal profession who do not have a broad experience with the range of head injuries common in accidental and inflicted injuries may not have as complete an understanding of the crossover between these types of terms, which may lead to frustration when the neurosurgeon is called as a witness. Several articles have been written that detail series of injury types resulting from various accidental mechanisms of injury in infants and young children, including falls from beds at home, falls from beds while in the hospital, and falls in stairways and from heights.⁸⁵⁻⁹⁰ Other authors have approached the question of what mechanisms cause what injury at what age by retrospective or prospective studies of

consecutively assessed children admitted or evaluated through emergency departments.^{15,31,91-93} These studies are remarkably consistent in that they show that, with the exception of epidural hematomas, low-height falls in children (generally from household surfaces with a head-to-impact distance of less than about 3 feet) do not result in life-threatening brain injuries. When small focal collections are interpreted on CT scans as subdural hemorrhages, they usually are found in infants who appear clinically well.^{84,91-93} This is why the history of a low-height fall in a child with an acute subdural hematoma and neurologic compromise is generally considered grounds to consider inflicted injury as a possible mechanism of injury.^{16,35,81,94}

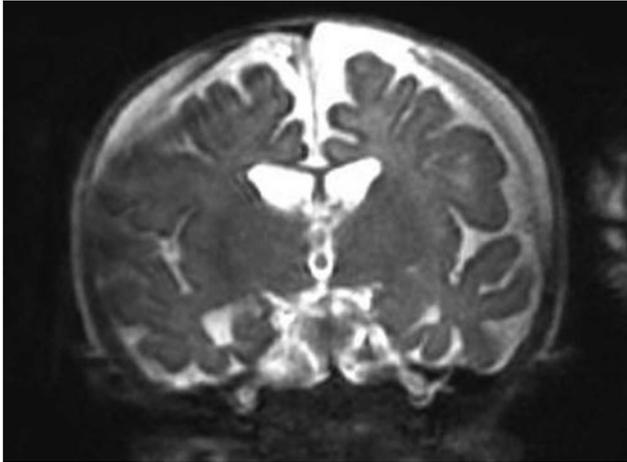

Fig. 52.4 Rapid T2-weighted magnetic resonance (MR) image, coronal view, showing bilateral subdural collections in an infant with an enlarging head. Rapid MR imaging techniques appear to be sensitive in visualizing subdural collections, can be performed without sedation or radiation exposure, and have gained increasing utilization for macrocephaly screening.

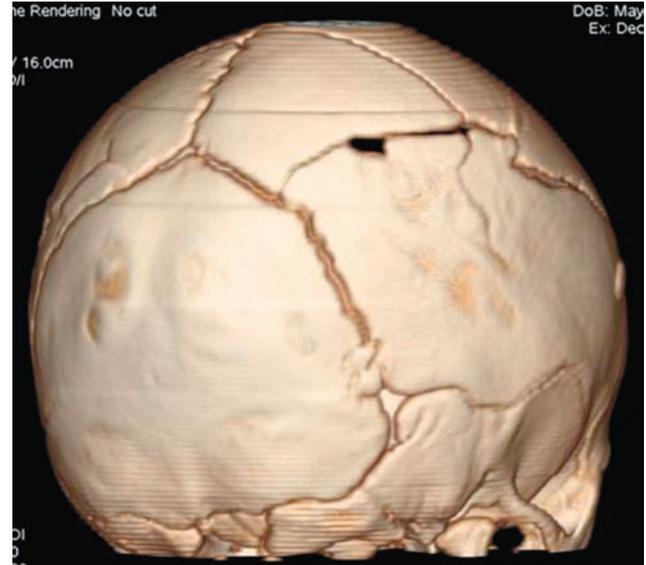

Fig. 52.6 Three-dimensional computed tomographic scan of a child with skull fractures after a reported fall in a bathtub. Note multiple complex fractures. The father later confessed to abuse.

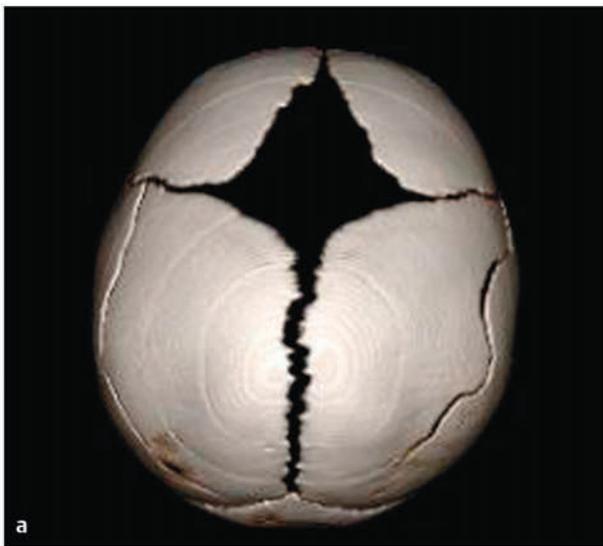

Fig. 52.5 (a,b) Three-dimensional computed tomographic scans of the head of a child dropped while being carried by its mother, who tripped over the family dog. The impact to the child's forehead caused bilateral parietal fractures. Images were acquired with a reduced radiation dose technique.

Fig. 52.7 “Contact” subdural injury. This 16-month-old toddler fell from the side of a basement stairway onto cement. She sustained a skull fracture and an underlying torn cortical vessel, resulting in an acute subdural hematoma, and was minimally responsive on presentation. After evacuation of the hematoma, she made a good neurologic recovery.

An exception to the wide body of literature cited above documenting the relative safety of low-height falls is a paper written by Plunkett that is often quoted by defense experts in inflicted injury cases.⁹⁵ This paper was a retrospective review of data on playground equipment collected by the U.S. Consumer Product Safety Commission (CPSC) National Injury Information Clearinghouse. Data were collected from selected U.S. hospital emergency departments to create a probability sample that could be used to assess consumer product-related injuries. A subset of these injuries underwent more in-depth investigations by CPSC staff. The author of the paper reviewed files in the database for head and neck injuries involving playground equipment that occurred from 1988 to 1999. He found 18 deaths due to falls in children ranging in age from 12 months to 13 years. The article profiles these cases, most of which involve falls from swings, ladders, and platforms. Distances, measured from the body part closest to the ground (not from the head to the ground), ranged from 2 to 10 feet. Most children had skull and/or scalp injuries, and the most common intracranial pathology was subdural hematoma with brain swelling; some children had contusions and/or epidural hemorrhages. In some children, the clinical symptoms were minor initially and then progressed over hours to days. Some children had retinal hemorrhages. About two-thirds of the patients had autopsies. The author concluded that “short-height” falls can cause fatal injuries in children, that

retinal hemorrhages can occur, and that a “lucid interval” may be present.

For neurosurgeons who deal with many traumatic injuries, none of these conclusions is surprising. However, there is a difference between these mechanisms and the histories given in many inflicted injury scenarios, which most often describe low-velocity falls from low heights, usually from a stationary reclining position, so that the distance the head falls is less than 2 feet (the average couch is about 18 inches in height). Playground falls typically happen in older children, there is often an initial velocity in addition to free fall acceleration (such as occurs on swings and seesaws or when children are jumping or swinging on bars), and the fall height of the head itself may be several feet greater than the distances cited for the body part closest to the ground. Contact and other types of subdural injuries (discussed further below), contusions, and intracranial lesions can indeed progress over time as brain swelling occurs, particularly if the seriousness of the injury is not initially recognized. Contusional swelling, hyponatremia, hypoventilation, and seizures can all contribute to a worsening clinical status. Retinal hemorrhages, seen in some of the children reported in Plunkett’s paper, have been previously documented in a number of accidental scenarios, particularly those associated with acute subdural hematoma.^{15,40,42,47}

Because subdural hematomas are so common in cases considered as possibly inflicted injuries, it is worth discussing briefly the different types of subdural hematomas with respect to what structures constitute the sources of hemorrhage and the different mechanisms involved. Although at least one neuropathologist has suggested that the subdural hemorrhages seen in inflicted injury might be due to hypoxia alone,⁹⁶ most researchers continue to assume that the hemorrhages are traumatic in origin. This assumption is based on the frequent finding of additional signs of mechanical injury, as well as the lack of subdural hemorrhage in most cases of hypoxia/ischemia in infancy with other causes. As described below, it may be that more than one mechanism is at work to explain the varied findings encountered.

Classically, convexity subdural hemorrhages in adults are thought to occur from rapid angular deceleration, in which the head stops moving but the brain continues to rotate within the skull. This causes stretching and ultimately rupture of the parasagittal bridging veins, which are avulsed from the cortical surface and bleed into both the subarachnoid and subdural space.^{97,98} In primate experiments, an anterior-posterior (sagittal) plane of rotation is the one most likely to result in bridging vein rupture, and a large magnitude of angular deceleration is required.⁹⁹ Despite the fact that case reports, mostly of older adults in motor vehicle collisions, have documented the occurrence of subdural hemorrhages without contact, in most cases of acute subdural hemorrhage in adults (especially in younger patients), contact is required to create the large angular deceleration forces necessary to rupture cortical bridging veins.^{3,80,99} Under conditions of lower magnitudes of angular deceleration (i.e., those that involve lower velocities and more gradual deceleration), the parasagittal veins may stretch but do not fail. Contrary to Caffey’s original descriptions, it has been reported that in the majority of cases of inflicted injury in infants and young children, signs of cranial impact are evident with careful radiologic and forensic techniques, including skull fractures and

scalp hematomas.^{24,100–102} When impact forces are dissipated over a wide area against a deformable skull, surface contact injuries may not be evident clinically or radiologically, or contact injury may not occur at all.

A great deal of effort has been expended by persons in the field of child maltreatment to address the question of whether shaking alone can or cannot cause serious injury in infants and young children. This question revolves around the specific mechanism of injury as well as the types and magnitude of forces and the injury threshold necessary for the particular types of injuries seen in cases suspicious for inflicted trauma to occur. There are arguments on both sides of this debate arising from clinical, medicolegal, and biomechanical sources.^{10,101–109} One factor that clouds the debate arises from the fact that many clinical and autopsy series concluding that shaking has occurred rest on the assumption that the absence of findings of impact necessarily implies that shaking took place. In fact, impact and rapid deceleration both may occur without visible sequelae of direct impact. This fact has been documented in series of children with clear accidental trauma.¹¹⁰

With respect to the *magnitude* of deceleration, biomechanical studies using anthropomorphic surrogates have shown that shaking alone appears to correlate with relatively small angular deceleration forces in comparison with inflicted impact to the head, with impact causing deceleration 30 to 50 times greater than that caused by vigorous shaking alone.^{24,103} The forces generated by shaking, when scaled for injury thresholds in young adult nonhuman primates, do not reach the concussion threshold. In contrast, impact events span the range of concussion, subdural hemorrhage, and even diffuse axonal injury.²⁴ Inflicted impact in a recently reported model of a 6-week-old infant was associated with significantly greater angular deceleration than that caused by a fall from 5 feet in which the head struck cement.¹⁰³

Finally, the question of whether infants and young children have a lower *threshold for injury* in the context of shaking compared with older children, adults, primates, and other sources of comparison is still under study. Some data from immature large animal models suggest that the threshold for axonal injury resulting from angular forces may be lower during immaturity, whereas younger subjects may be more resistant to damage from focal injury and subdural hematoma.^{111–113}

At present, although different opinions exist, it is probably accurate to say that the exact mechanism and threshold necessary to cause *any* injury to the intracranial contents, as well as the amount and type necessary to cause *severe or fatal* brain injury, remain incompletely understood. This is particularly true when the contributions of repetitive injury, hypoxic/ischemic insult, and/or cervical spine injury are also taken into account.^{60,67,78,107,111,114–116} This is not to say, however, that nothing has been learned about mechanisms of injury and the typical sequelae of injury, as will be further discussed below.

Finally, challenges have been raised about whether the presence of subdural hemorrhage necessarily implies a traumatic mechanism or whether subdural bleeding can occur from hypoxic/ischemic stress, coughing, or vomiting.^{96,117} Although such explanations have been proposed, and some autopsy cases used to explore these possibilities, to date such occurrences do not fully match the types of clinical injuries typically seen in suspected cases of inflicted injury, and these mechanisms have not been found to be associated with subdural hemorrhage in

series of children with medical conditions causing repeated coughing or vomiting.¹¹⁸

In acute inflicted injuries, although the questions of which vessels rupture and what mechanisms are required to cause acute subdural hemorrhage are still debated, it seems likely that different mechanisms may be at play in different cases.^{11,96} Chronic subdural collections are even more problematic with respect to mechanism; the likelihood of a nonaccidental etiology for chronic collections remains a matter of debate, with estimates ranging from 46 to 68%.^{94,119} In elderly patients with cortical atrophy or children with shunted hydrocephalus, it has been observed that relatively mild blows to the head may result in subdural hemorrhage; it is generally hypothesized that enlargement of the subarachnoid space results in greater stretch of the bridging vessels. However, in children with so-called “benign external hydrocephalus,” in which the subarachnoid spaces are enlarged, subdural hemorrhage appears to occur rarely.^{64,120} Whether small collections that are minimally symptomatic may predispose to recurrent bleeding, with symptom onset after relatively mild trauma, remains a point of debate in the defense world. However, the frequency with which young children fall repeatedly without catastrophic hemorrhage seems to argue against this “two in a row” explanation for serious brain injuries potentially resulting from low-height falls. The term *second impact syndrome* is used to describe the rare occurrence of highly morbid or fatal consequences after repeated sports-related contact injuries in adolescents and young adults.^{121–123} These athletes are found to have subdural hemorrhages and/or severe acute brain swelling accompanied by acute unconsciousness immediately or within minutes of second contact. To date, there is no convincing evidence of a similar phenomenon resulting from low-height falls (less than 3 to 4 feet) in infants and young children.⁶⁴

One difference between infants and older children and adults is the relative deformability of the infant skull. Thus, other surface vessels besides the parasagittal bridging veins may be stretched or torn during certain kinds of events. Small convexity, posterior fossa, and tentorial subdural hemorrhages may occur during birth, and skull deformation from static loading during crush injuries may lead to collections at these sites.^{124,125} It has been hypothesized that deformation of the back of the head due to inflicted impact might rupture posterior draining veins, thus accounting for the high frequency of posterior interhemispheric fissure hemorrhages.¹¹ In a series of infants younger than 2 years of age with subdural hemorrhages due to motor vehicle collisions, skull fractures were seen in the majority, and half had other types of parenchymal brain injury and varying levels of depressed consciousness. The subdural collections were seen most commonly along the falx and frontoparietal convexities, and retinal hemorrhages were sometimes seen.¹²⁶

Other mechanisms that can cause subdural bleeding include contact subdural injuries, which can occur in adults and children from a focal blow over a cortical vessel (► Fig. 52.4). Venous epidural hemorrhages, usually associated with fractures, may be indistinguishable from subdural hemorrhages on CT scan. So-called “disappearing subdurals” may occur in children after falls and likely represent focal subarachnoid hemorrhages that are diluted rapidly and resolve over a day or two after injury.⁸⁴

In summary, acute subdural hemorrhages in infants and young children that are accompanied by significant acute neurologic deficits (such as coma) appear to result from accidental

mechanisms that require more force than those associated with low-height free falls. Although exact thresholds are still not available, there are clinical and experimental data to indicate that free falls from heights such as those of furniture (head-to-floor distance not more than about 3 feet) can cause skull fractures, epidural hematomas, and perhaps other focal extra-axial collections, but they do not appear to be sufficient explanation for the phenomenon of acute subdural hematoma, brain swelling, and death.^{15,32,81,91,92,103}

52.6 Treatment

The medical and surgical management of acute inflicted brain injury is no different from that for injury associated with other mechanisms. It may be helpful to note that an infant who does not cry or show a vigorous facial expression to a trapezius pinch or other painful stimulation is likely to have a significant depression of cortical activity, which may be reflective of severe injury.⁸³ The general principles of airway, breathing, and circulatory support apply to these patients. Collaboration with colleagues in general surgery can minimize the chance of missing additional injuries, such as abdominal trauma. Serial routine laboratory tests, including hemoglobin, electrolytes, and coagulation studies, will help identify evolving complications.¹²⁷

Because seizures are common and may have subtle clinical manifestations, anticonvulsants should be considered even if seizures are not clinically apparent.^{9,26,59} Hemorrhages with significant mass effect are uncommon, but in this instance, evacuation may be considered. Some authors advocate creating “dural slits” to allow blood to extrude without creating difficulty in closure because of excessive brain swelling. Others have used decompressive craniectomy as a way of managing brain swelling, which may be considerable in these cases.^{128–130} Although prospective trials are lacking, early hemicraniectomy may help limit damage to the contralateral hemisphere in cases of unilateral severe damage with brain swelling (unilateral “big black brain”)^{60,130} (► Fig. 52.2).

As previously mentioned, the poor outcome seen in many patients with inflicted head injuries, particularly those with bilateral diffuse hypodensity, may influence the degree to which extraordinary interventions are applied.^{63,131} Elevations in cerebrospinal fluid markers of brain injury are particularly pronounced in infants with inflicted injury if they have previously been treated with ventriculostomy; whether this reflects a specific vulnerability related to patient age or the significant parenchymal damage from trauma and/or hypoxia/ischemia remains uncertain.^{132,133}

52.7 The Role of the Neurosurgeon in the Medicolegal Investigation of Inflicted Injury

Most children's hospitals and academic medical centers have a child protection team that takes on the responsibility of investigating and reporting suspected abuse. The neurosurgeon may be asked to consult as to whether a given patient's injuries appear consistent with the mechanism reported. Several workers in the field have attempted to address this problem with sys-

tematic approaches or algorithms to assist in this determination, based on the body of clinical and experimental evidence surveyed in previous sections.^{15,81,134,135}

Clinicians may be requested or required to participate in civil or criminal proceedings. Civil proceedings generally deal with the disposition of the child, whereas criminal cases determine if a crime has been committed and by whom. It should be kept in mind that the level of suspicion for inflicted injury determined by the medical team typically falls into one of three main categories: consistent with accidental trauma, presumptive for inflicted injury, or “suspicious but not presumptive (indeterminate).” Part of the conflict that often occurs between the medical and legal professions in this arena arises from the general principle that the medical team tends to use three categories of level of suspicion, whereas the legal system tends to prefer a more dichotomous determination, particularly in criminal matters. Thus, the neurosurgeon may feel pressured into saying “it was” or “it wasn't” abuse, when the most honest and complete answer in a particular case is “it may have been, but we can't tell for sure.” Although the intermediate category may not be sufficient for criminal prosecution, it by no means precludes child protective service involvement, with the goal of keeping the patient and/or other children safe from harm. In criminal proceedings, questions about the degree of certainty regarding the etiology of the findings are common. In addition, in order to prosecute or defend specific individuals, questions about forces required, intent, alternate explanations, timing, and the possibility of a “lucid interval” during which the accused may have simply unwittingly taken over care are frequently raised.^{11,64,136}

With respect to court appearances, neurosurgeons may be called as fact witnesses or as expert witnesses. In some states this distinction is clear, and the treating physician can decline to comment on any but the basic facts of the case relevant to his or her care of the child. In other states, the treating physician can be admitted as an expert by the judge even if he or she has requested to provide fact witness testimony only, and can be compelled to provide opinions on the mechanisms responsible for the injuries to the child.¹³⁷ It may be helpful under these circumstances to keep in mind that the field of inflicted head injury is a specialized and controversy-ridden one, and that to expect all neurosurgeons to be fully familiar with all the relevant clinical and basic research is unreasonable. The physician and patient are best served when the witness provides a full and accurate testimony without speculation and resists being pressured into conjecture or “best guess” answers, especially if the experience of the witness in this aspect of the field is limited. Conversely, when the injury syndrome is clearly consistent with inflicted injury (e.g., healing skeletal fractures, acute life-threatening subdural hemorrhage with evidence of contact injury, severe bilateral retinal hemorrhages, and no history of trauma), the neurosurgeon can express these views with confidence.

52.8 Prevention

As understanding of inflicted injuries in infants and young children has evolved, prevention efforts have changed, as well. Early campaigns were directed at parents, particularly mothers, to educate them to “never ever shake a baby,” usually via pamphlets and other educational materials provided at well-child checkups.^{138,139} Home visits to at-risk families of newborns

have received increasing attention as a preventative strategy.¹⁴⁰ More recent efforts have focused on the neonatal period; mandatory education is provided while infants are still in the newborn nursery, and both parents are encouraged to sign a contract promising that they will not use physical force when frustrated by crying or other infant behavior.¹⁴¹ Because many perpetrators are male friends of the mothers of infants, other potential targets for prevention efforts would seem to be young men, perhaps through a school setting, and mothers, who need to be educated to be cautious when deciding to leave their infants in the care of a boyfriend.

52.9 Conclusion

Although it is tempting to be nihilistic about inflicted head injuries, it is probably fair to say that aggressive management in infants who do not present with bilateral diffuse hypodensity likely improves outcome, as it does in accidental head injuries.^{60,142} Over time, more research and open-minded data gathering and analysis will help shed light on the necessary forces and circumstances required to cause different types of injuries in children of different ages. However, at present, the diagnosis of inflicted injury rests on a constellation of specific findings in association with a specific history or lack thereof. As in accidental trauma, prevention is key. The neurosurgeon plays a significant role here both in prevention efforts in general and in preventing injuries to other children who might be the next victim of an unrecognized perpetrator. Objectivity and compassion for the patient, family, and potential future victims must all be brought to bear in these difficult cases.

Pearls

- Inflicted injury is the most common cause of traumatic mortality in infants.
- The most common constellation of findings in children with inflicted head injury includes subdural hemorrhages with or without scalp contusion, skull fracture, retinal hemorrhage, and skeletal injury.
- Because children may present with a variety of injury types resulting from a variety of mechanistic causes, the terms *inflicted injury* and *nonaccidental injury* are preferable to those implying a specific single mechanism (such as *shaken baby syndrome*).
- The most common history is no history of trauma (infant presenting because of symptoms such as lethargy or seizures) or a history of a short-height free fall.
- Infants may present with varying levels of consciousness, ranging from normal to comatose. An infant who does not cry or grimace in response to painful stimulation can be considered to have cortical impairment.
- Apnea and seizures are common, and seizures may be subclinical.
- Infants who present with unresponsiveness and whose imaging shows bilateral hemispheric hypodensity have high morbidity rates and uniformly poor outcomes. Infants with lesser degrees of injury have variable outcomes. Early hemicraniectomy has gained increasing use in children with the unilateral form of severe brain swelling associated with subdural hematoma.

53 Accidental Head Injuries in Children

Brandon G. Gaynor, Garrett K. Zoeller, and John Ragheb

The management of traumatic injuries has been the focus of medical writings since the earliest known medical document—the Edwin Smith Surgical Papyrus.¹ This 3,000-year-old papyrus contains the writings of the ancient Egyptian physician Imhotep, in which he details the rational management of 48 medical cases, 27 of which are cases of traumatic injury. Our current medical practice can be traced back to Imhotep's rational, experienced (“evidence-based”) approach to medicine.

This chapter focuses on accidental head injuries in children, drawing from the literature and the recently updated “Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents—Second Edition.”² The incidence, mechanisms, and outcomes of accidental traumatic brain injury (TBI) in children are distinct from those in adults and vary with the age of the child. They also vary from those of nonaccidental TBI in children, who likely represent a unique and distinct group and are reviewed in Chapter 52. In addition, the physiologic and pathophysiologic responses of children to trauma vary with age, and therefore management must be age-specific. A practical approach to the diagnosis and management of accidental traumatic injuries to the developing nervous system is presented in this chapter. Other chapters in the section on trauma deal specifically with such topics as penetrating head injuries, hematomas, critical care management, rehabilitation, and outcomes.

53.1 Epidemiology

Unintentional injuries are the leading cause of death in children. They account for at least a third of deaths in children aged 1 to 14 years and half of those in older adolescents.³ Of all types of traumatic injuries, those to the brain are the most likely to result in death or permanent disability. Among children aged 0 to 14 years, TBI results in an estimated 2,174 deaths annually, 35,135 hospitalizations, and 473,947 emergency department (ED) visits. The annual death rate from traumatic injury in children younger than 4 years is 5 per 100,000. The death rate is higher for children younger than 4 years than for those 5 to 14 years of age. The higher traumatic injury death rate in younger children may sadly reflect the number of inflicted injuries in infants and young children because these figures do not distinguish accidental injury from abusive injury. In adolescents and young adults 15 to 19 years of age, the death rate rises to 19 per 100,000, approaching the rate of death by TBI for young adults.⁴

The most common mechanisms of pediatric TBI vary by age group. Developmental milestones for movement and ambulation are reflected in the way children are injured. Falls are the leading cause of TBI in children younger than 14 years.⁵ Children younger than 4 years of age are injured primarily by falls but are also vulnerable to inflicted injuries and motor vehicle crashes. Children 4 to 8 years of age are injured in falls and motor vehicle crashes but also become more at risk for other transportation-related injuries (e.g., bicycles, as pedestrians struck

by cars, etc.). The leading cause of death past the age of 14 is motor vehicle crashes, which kill more teenagers than all other causes combined.^{6,7}

53.2 Types of Accidental Head Injuries

Accidental head injuries in children result in a spectrum of traumatic injuries to the scalp, skull, meninges, and brain that are comparable to those in adults but differ in both pathophysiology and management. The highly vascular scalp is a potential source of major blood loss. Whereas a small loss of blood volume in an adult trauma victim can be trivial, the same blood loss can readily lead to hemorrhagic shock in a newborn, infant, or toddler. This may occur without overt external bleeding in infants and young children. By that token, the presumed plasticity of the brain that is lost with development may provide an outcome advantage for the developing brain compared with its adult counterpart.

Advances in technology impact the delivery of medicine by helping physicians to efficiently evaluate, diagnose, and transfer severely injured patients. Computed tomography (CT) has become widely available and affordable. The luxury of such technology should augment, not substitute for, clinical skills and judgment. It is estimated that for every 700 head CTs ordered, one additional fatal cancer occurs that can be attributed to radiation exposure.⁸ The judicious use of CT screening and follow-up examinations is important for cost control and patient safety. A recent prospective study of 42,412 children with minor blunt head trauma conducted by the Pediatric Emergency Care Applied Research Network (PECARN) validated a set of predictive rules to identify children who can be observed without CT. Among patients without altered mental status, scalp hematoma, loss of consciousness, severe mechanism of injury, signs of skull fracture, severe headache, or abnormal behavior, fewer than 0.05% had a clinically significant TBI.⁹ It is likely that a significant portion of CT examinations ordered for children by EDs may not be medically necessary.

The incidence of cervical spine injury in the pediatric population with blunt trauma in the National Emergency X-radiography Utilization Study in Blunt Cervical Trauma (NEXUS) was 1%.¹⁰ Although rare, the morbidity and mortality associated with spinal cord injury require accurate and rapid identification of affected patients. The biomechanics of the developing spine also predispose young children to spinal cord injury without radiographic abnormality (SCIWORA).¹¹ The Trauma Association of Canada (TAC) has recently published the first evidenced-based consensus guidelines for clearance of the cervical spine in pediatric trauma patients. These guidelines recommend applying NEXUS criteria with the addition of 45-degree neck rotation in order to clear the cervical spine, reserving CT or magnetic resonance (MR) imaging for those with abnormalities on X-ray and neurologic examination or with neck pain. Validation of these guidelines with prospective data is expected to take several years.¹²

53.2.1 Injuries to the Developing Skull

The developing skull is thinner, more pliable, and more easily deformed than its mature counterpart. Open sutures provide the skull with some movement and can offset some rise in intracranial pressure (ICP) by expanding the intracranial volume.¹³ Skull injuries can be classified as nondepressed (linear), depressed, elevated, basilar, or growing.

Linear Skull Fractures

Skull fractures are common injuries in young children. Linear skull fractures are the most common abnormal radiographic findings identified in children after head injury.¹⁴ Linear fractures in children may be associated with hemorrhage or significant underlying brain injury, but they usually are not. Complex fractures (i.e., those that are multiple or stellate or that cross a venous sinus) are more likely to be associated with an underlying brain injury or hemorrhage.

Linear fractures represent an injury of sufficient energy that has been dissipated by the skull. The vast majority of linear skull fractures in young children are caused by falls. Anyone who has spent time with toddlers or young children recognizes that falls are extremely common events, even in those younger than 6 months. In a large population-based survey study of 11,466 infants younger than 6 months, there were 3,357 falls in 2,557 children. Despite the large number of falls, of which 53% were from a bed or a piece of furniture, only 21 falls (<1%), resulted in a concussion or a fracture.¹⁵

Linear skull fractures can readily be diagnosed by plain radiography; however, the role of plain radiography in trauma is limited. Clinical criteria should be used to distinguish those patients with risk factors significant enough to warrant computed tomography (CT) from those who can safely be observed without imaging. The importance of a linear fracture is the potential for an associated intracranial pathology.^{16–18} Because of ease of acquisition, availability, relatively low cost, and high sensitivity, CT is the standard test to identify intracranial hemorrhage and fracture in children with significant head injury.^{19,20} Occasionally, CT will miss an axially oriented fracture that falls within the plane of the CT scans. Although uncommon, this problem can be avoided by careful inspection of the CT scan scout image.

The vast majority of linear skull fractures require no treatment and heal without sequelae. Children with an isolated, uncomplicated skull fracture and a normal neurologic examination do not require hospital admission. They can be followed at home after a brief period of observation in the ED, provided that the home situation is reliable and caregivers can return promptly in the unlikely event that deterioration occurs. Admission is prudent for patients with persistent vomiting, significant scalp swelling (which can lead to anemia, especially in infants younger than 6 months of age), neurologic deficits, intracranial injury on CT, or suspicion of child abuse.^{21–23}

Growing Skull Fractures/Leptomeningeal Cysts

Growing skull fractures, or leptomeningeal cysts, are a rare but well-recognized complication, occurring in approximately 1% of children with skull fractures.²⁴ Skull fractures associated

with an underlying dural laceration are the essential substrate of growing skull fractures.²⁵ The growing brain, or perhaps simply the normal pulsations of the brain transmitted through cerebrospinal fluid (CSF), results in herniation of the brain through a dural laceration. Over weeks to months, the edges of the fracture are eroded and/or remodeled, becoming smooth and widening (much as a flowing river erodes its banks). The most common location for growing skull fractures is the parietal region, but they have been described in the orbit and posterior fossa,²⁶ skull base, and anterior fontanel,²⁷ and also as a complication of craniofacial surgery.²⁸ A growing skull fracture presents as a soft, pulsatile mass beneath the scalp, with seizures, or with a progressive neurologic deficit. The diagnosis can be made by skull X-ray in most cases. CT and MR imaging are more sensitive in diagnosing growing skull fractures and can be helpful in identifying the presence of hydrocephalus or an associated porencephalic cyst.²⁹ The treatment of growing skull fractures involves repair of the dura, which invariably requires a dural graft. The dural defect always exceeds the bone defect, which must be taken into consideration when the craniotomy flap is planned. Cranioplasty is also necessary and should be performed with autologous bone whenever possible. A shunt is indicated only when there is associated hydrocephalus, not as a primary treatment for a growing skull fracture. Growing skull fractures should not be allowed to go untreated because the delayed onset of neurologic complications and cranial deformity have been reported.³⁰

Depressed Skull Fractures

Depressed skull fractures are relatively common in children, accounting for approximately 10% of all skull fractures.³¹ Like linear fractures, most depressed fractures, in which the scalp is intact, do not require surgical intervention. This nonsurgical approach does not appear to increase the risk for seizures or neurologic dysfunction, or to result in greater cosmetic deformity.³² Exceptions may be fractures with a suspected dural laceration or significant underlying brain injury, or fractures in locations of cosmetic importance. A unique subset of depressed fractures in infants and neonates are known as ping-pong fractures. Usually, ping-pong fractures are the result of traumatic deliveries, malpositioned forceps deliveries, or short-distance falls. Most ping-pong fractures involve the parietal bone. When small, these fractures will frequently remodel under the influence of the rapidly growing infant brain without intervention. Although the complication rates are similar for simple depressed skull fractures whether they are treated with observation or surgery, the application of a breast pump or vacuum suction has been reported to be a safe and effective alternative for achieving prompt recovery.³³ Larger ping-pong fractures are easily elevated with a small linear incision, a bur hole, and a Penfield elevator, relieving the anxiety many new parents experience while waiting for the deformity to remodel on its own.

Compound or open depressed skull fractures (i.e., those in which the scalp is lacerated) should in most cases be explored, debrided, and repaired. Compound fractures are more often associated with an underlying dural or brain injury and a worse overall prognosis.³⁴ Repair of a compound depressed

skull fracture should include a return of the bone fragments to the defect whenever possible. This approach does not appear to increase the risk for postoperative infection and avoids the need for cranioplasty in the future.³⁵ Prophylactic antibiotics beyond the immediate perioperative period, although used frequently in practice, do not appear to reduce the risk for infection.³⁶

A variation of the depressed skull fracture known as an elevated skull fracture has also been described. Elevated skull fractures result from a high-energy impact with a sharp object that elevates the flap by lateral and tangential force vectors or from direct retrieval of a sharp weapon. Once thought to occur only in adults, elevated skull fractures have been reported in children. These unusual fractures are almost always compound and should be managed as a compound depressed fracture with early debridement, reduction, and repair of the underlying dura. Patients with fractures due to a severe mechanism often present with neurologic complications; however, delayed deterioration is also a risk with simple elevated fractures.^{37,38}

Basilar Skull Fractures

Basilar skull fractures occur in children at approximately the same frequency as in adults, accounting for 15 to 19% of skull fractures.³⁹ CSF leak, via the ear or nose, occurs in about a quarter of the cases and most often stops without intervention. Elevating the head, as well as avoiding straining or any manipulation of the ear or nose, is usually all that is required. In those children (approximately 20%) in whom the leak persists beyond the second or third day after injury, a lumbar drain may be used if not otherwise contraindicated. Prophylactic antibiotics play no role in preventing meningitis in patients with a posttraumatic CSF leak, and their use may actually result in infection by unusual or drug-resistant organisms.⁴⁰⁻⁴²

Persistent CSF leak after a basilar skull fracture that does not respond to a trial of lumbar drainage requires surgical repair. The presurgical assessment should include MR imaging, which is used to exclude posttraumatic hydrocephalus as well as to visualize the site of the leak. Disruption of the skull base or posterior wall of the frontal sinus and leakage of CSF through a dural defect are readily seen on T2-weighted MR imaging. Thin-section CT is also useful to assess fractures of the skull base and for surgical planning, but it is not a reliable method to identify the site of CSF leak. Radioisotope cisternography with nasal pledgets and CT after contrast cisternography can be used to identify the presence and location of a CSF leak, respectively, but are now rarely needed in the era of MR imaging. Operative repair requires adequate exposure of the fracture site, dural repair, and depending on the size of the fracture defect, a bone graft to support the duraplasty and reconstruct the skull base. Lumbar drainage can be helpful to obtain adequate exposure of the fracture site and to decrease the chance of a persistent CSF leak through the dural repair.

All of the structures of the skull base are potentially at risk after a fracture of the skull base. The carotid artery, venous sinus, cranial nerves, and middle ear structures may be injured, and depending on the location of the fracture, attention should be given to the structures at risk based on the course of the fracture.

53.2.2 Injuries to the Developing Brain

TBIs can be divided into primary and secondary injuries, as well as injuries that are focal or diffuse. Primary TBIs are those injuries that are a direct result of the dissipation of the energy of the traumatic force in the brain. Examples of primary brain injuries are contusion, laceration, hemorrhage, and axonal disruption. Secondary brain injuries result from factors that cause further damage to the brain; these occur as a response to, or result of, the primary traumatic injury and the physiologic derangements that follow. Secondary insults or the contributors to secondary injury are hypoxemia, hypotension, cerebral edema, and elevated ICP.

Traumatic Intraparenchymal Hemorrhage

Traumatic intraparenchymal hemorrhages, also known as brain contusions, are primary brain injuries that result from direct trauma to the brain at the point of impact. Focal contusions may also be the result of impact from an overlying fracture or a deceleration injury as the moving brain strikes the inner table of the skull. The injuries may occur at the point of impact (*coup*) or opposite the point of impact (*contrecoup*). Typically, focal contusions occur over the basal frontal or petrous regions and the frontal or temporal poles. The vast majority of focal hemorrhagic contusions do not require surgical intervention unless they are associated with a compound fracture or if they are of sufficient size to require evacuation. Serial CT and close neurologic observation in a monitored setting are required for patients with focal hemorrhagic contusions. A retrospective cohort found that 28.5% of patients with abnormalities on initial CT who underwent repeated examinations within 24 hours had had a radiographic progression. Intraparenchymal, subdural, and epidural hematomas or cerebral edema should be managed as a high risk for deterioration.⁴³

Concussion and Diffuse Axonal Injury

Diffuse injuries to the brain are the result of deceleration or angular acceleration injuries to the head. The spectrum of diffuse brain injury ranges from subclinical concussion to severe diffuse axonal injury. In its mildest form, diffuse brain injury is exemplified by the remarkably common concussion. It has been estimated that 144,000 ED visits for children younger than 19 years have a discharge diagnosis of concussion.⁴⁴

The hallmark of concussion is a brief (seconds to minutes) loss of consciousness. Although a loss of consciousness is sufficient to diagnose concussion, it is not necessary. CT of the brain is usually normal. There can be a period of confusion or amnesia afterward. Concussion is frequently associated with vomiting in children, which may necessitate admission to the hospital. Efforts have been made to grade the severity of concussion based on the length of loss of consciousness, the presence and duration of amnesia, and errors in mentation.⁴⁵⁻⁴⁷ The subtle cognitive, neuropsychological, and physical consequences of concussion are now recognized more often as a result of the development of grading systems, but none of the grading scales has been validated in children. The sequelae are more readily identified after repeated concussions and, not surprisingly, in those who are more thoroughly tested.

Growing public awareness of concussion and perceived “minor” TBIs has been accompanied by a rise in ED visits for sports-related TBIs in the United States. In 2009, there were 248,418 ED visits for sports-related TBIs, an increase of 62% from 2001. Seventy-one percent of patients seen in the ED for recreational or sports-related TBIs are male. Activities associated with the highest incidence of nonfatal TBIs from 2001 to 2009, according to data from the Centers for Disease Control, are bicycling, football, playground activities, basketball, and soccer. However, the number of mild and nonfatal TBIs is likely much higher because these statistics do not account for the many unreported or unrecognized injuries.⁴⁸

Concern exists regarding the cumulative effects of repeated concussion and the risk for catastrophic “second-impact” types of injury. The long-term sequelae of a single concussion on the developing brain are unknown, although most patients are expected to make a full recovery. Evidence-based guidelines for the management of concussion are lacking, but cognitive and physical rest with a gradual return to activity and careful observation of symptoms are advocated. Children should not return to activities that entail a risk for further injury until their memory, behavior, cognition, and neurologic examination have returned to normal.^{49,50} Difficulty arises with young, overachieving athletes and their parents, who insist on putting themselves at risk for further injury by returning to play. There is room for better collaboration among schools, parents, coaches, and physicians to minimize the impact of concussion. Recognition of this fact has resulted in the passage of laws in most states mandating the evaluation of any school-aged athlete suspected of having a concussion and clearance before the athlete may return to play.⁵⁰

On the continuum of diffuse brain injury, at the opposite end of the spectrum from the simple, uncomplicated concussion is diffuse axonal injury. This is thought to be caused by shearing forces between gray and white matter or within subcortical regions as a result of rotational or angular acceleration and deceleration forces. In the early days of CT, patients with diffuse axonal injury presented in a coma with abnormal posturing. Their CT scans were described as normal or as exhibiting small punctate hemorrhages of the gray–white junction, brainstem, or corpus callosum. Today, the diffuse nature of this type of injury is readily evident on MR imaging, which can reveal widespread punctate areas of signal abnormality or subtle hemorrhage felt to reflect axonal injury.⁵¹

Patients with diffuse axonal injury are usually the victims of high-velocity crashes; children with this injury are typically pedestrians or cyclists hit by cars, or passengers in motor vehicles involved in high-speed crashes. In infants and toddlers, these mechanisms may also be associated with craniocervical injuries because of the large size of the head relative to the body, lax spinal ligaments, and relatively weak cervical musculature. Victims of diffuse axonal injury are unresponsive or posturing at presentation and may have cranial nerve signs. ICP monitoring is indicated in those patients with a Glasgow Coma Scale score of 8 or less, although it is usually not elevated in diffuse axonal injury.^{52,53} Recovery after diffuse axonal injury is slow, protracted, and usually incomplete. Although not practical in the acute setting, outcomes research on MR abnormalities with techniques like diffusion tensor imaging and functional MR imaging is warranted.

The neurosurgical management of brain injury in children focuses on the preservation of function. Aside from injury prevention, the essence of treatment is the prevention or control of secondary injury to the brain that is precipitated by the initial trauma. The critical care management of TBI is discussed in Chapter 56. The cornerstone of the neurosurgical management of TBI is ICP control. ICP monitoring in infants and children differs from that in adults in both techniques used and thresholds for intervention. Normal ICP in children is not the same as in adults, and therefore lower ICP thresholds may be used, but it has yet to be studied whether more aggressive treatment thresholds positively affect outcome in children. The guidelines support a Level 3 option of using 20 mm Hg as the cutoff for treatment.² In infants and toddlers, techniques of ICP monitoring that require placement of a “bolt” or a threaded device secured in the skull may not be feasible. The thin skull of an infant or young child may not provide adequate purchase for the threads of the device to be secured in the skull; however, many widely used devices have alternatives for tunneling. The gold standard technique of ICP monitoring remains placement of a ventriculostomy catheter. External ventricular drains offer both ICP monitoring and the therapeutic option of CSF drainage. Continuous drainage, however, sacrifices real-time ICP monitoring and may be supplemented with a separate ICP monitor or the use of an external ventricular drain that is coupled with a fiberoptic monitor. Infection can be minimized with meticulous technique, diligent nursing care, and the use of an antibiotic-impregnated external ventricular catheter whenever possible.⁵⁴

Surgical procedures to control medically refractory elevated ICP should be tailored to the individual pathology and maximize cranial volume. Data suggest that decompressive craniectomy reduces ICP and may be useful for treating medically refractory elevations in ICP.^{55,56} Current guidelines list decompressive craniectomy with duraplasty as an option for patients with early signs of herniation or medically refractory intracranial hypertension.^{2,57} Although the type of procedure that works best is unclear (unilateral vs. bilateral craniectomy, duraplasty vs. no duraplasty), it appears that decompression procedures should be reserved for patients considered salvageable. This may include patients who deteriorate neurologically without a focal mass lesion and who have either unilateral or bilateral hemispheric swelling. This scenario of hemispheric swelling is exacerbated by impaired autoregulation and is not uncommon in infants after nonaccidental trauma.⁵⁸

53.3 Complications: Seizures

Seizures complicate head injuries in children at least as often as in adults, at a rate of approximately 5 to 12%, although younger children may be more susceptible.^{59,60} The incidence may be higher for those with the most severe TBIs.⁶¹ The vast majority of seizures after head injury are impact seizures, which occur within the first 24 hours after injury. Early posttraumatic seizures are associated with worse outcomes and greater severity of injury. Some observational studies have found seizure prophylaxis with antiepileptic drugs to be protective for early seizures but not for posttraumatic epilepsy.⁶²

53.4 Conclusion

TBIs are the most common cause of death in young people and therefore represent a significant public health problem and a medical challenge. Concussions, which are now recognized as a brain injury, may have significant cumulative sequelae, and effort should be made to protect the child with a concussion from further injury. The best treatment is prevention. It is hoped that injury awareness education programs like ThinkFirst (www.thinkfirst.org) and universal seat belt laws and helmet laws for children will reduce cases of TBI in our society. Advances in critical care medicine, cerebral monitoring, and the control of secondary brain injury will offer the greatest potential in the future to limit the consequences of TBIs. Neurosurgical intervention remains the cornerstone of treatment for TBIs, allowing the rapid identification and management of mass lesions, the control of secondary injury, and the monitoring and management of elevated ICP.

Pearls

- CT is a source of significant radiation exposure to children and is most useful in patients with altered mental status or behavior, scalp hematoma, loss of consciousness, severe mechanism of injury, evidence of skull fracture, or severe headache.
- Growing public awareness of concussion and perceived “minor” TBIs has been accompanied by a rise in ED visits for sports-related TBIs in the United States.
- Current guidelines list decompressive craniectomy with duraplasty as an option for patients with early signs of herniation or medically refractory intracranial hypertension.
- TBI is the most common cause of death in young people and therefore represents a significant public health problem and a medical challenge.

54 Penetrating Craniocerebral Injuries

Ira E. Bowen, J. Gordon McComb, and Mark D. Krieger

Although not as common as closed head injuries, pediatric penetrating craniocerebral injuries (PCIs) account for significant morbidity and mortality within the pediatric population. Neurosurgeons are often presented with difficult management decisions when treating children with PCIs. Although many neurosurgical techniques and principles apply, several unique factors require further consideration. In this chapter, we summarize the current epidemiology, pathogenesis, diagnostic evaluation, and treatment measures available to the pediatric PCI population. Special attention is directed toward surgical management and the prevention and treatment of complications.

54.1 Epidemiology

Emergency neurosurgical admissions for pediatric PCIs are on the rise in the United States. A recent study reported a 138% increase in pediatric PCIs in the last decade, as well as a 4% rise in pediatric gunshot wounds to the head.¹ The true incidence is hard to quantify because of several factors, including the lack of a centralized database and the likelihood that victims incurring PCIs may die before reaching the emergency department (ED).² Additionally, many of these patients have been excluded from studies of head injuries, which tend to focus on closed head injuries. A study from Ontario, Canada, of all deaths from blunt or penetrating head injury in children younger than 16 years of age during the period from 2001 to 2003 found that only 12 of 234 deaths were caused by penetrating injuries.³ PCIs can be attributed to five overall causes: (1) accidental injury with sharp or semisharp objects, (2) warfare, (3) accidental discharge of firearms, (4) suicide, and (5) homicide.

In the pediatric population, PCIs can be attributed to countless random objects. Case reports have been written of PCIs caused by pencils and chopsticks,⁴ broom handles,⁵ metal strips, plant branches, kitchen knives, dinner forks, wires, nails, spikes, scissors, screwdrivers,⁶ and even a potato peeler.⁷ Often, flying debris during automobile accidents is a mechanism of PCI.⁸ Furthermore, low-velocity projectiles, such as arrows, BBs, and pellets discharged from pneumatic “toy” weapons, can be included in the category of causes of accidental injury.^{9,10} There are two key factors to consider in the management of impalements: first, penetration through thin calvarial regions is frequently associated with a high risk for vascular or cranial nerve damage, and second, retained foreign bodies (especially radiolucent objects) increase the risk for infection.

Throughout history, the pediatric population has been plagued by warfare, with countless injuries to both innocent children and young soldiers. Two Iranian series of traumatic aneurysms, detailing the effects of military PCIs on the pediatric population, reported that 25% of patients were 18 years of age or younger.^{11,12} Furthermore, a recent study of a field hospital in Iraq found 52% of pediatric consultations to be related to PCIs.¹³ It is of note, however, that unlike most civilian PCIs, those incurred during warfare are caused mainly by shrapnel rather than bullets, and when they are caused by bullets, the bullets tend to be high-velocity bullets associated with a much higher

mortality.¹⁴ Therefore, when the treatments and outcomes of PBI are studied, it is worth distinguishing between military and civilian populations. Because of the practical applications of this textbook, emphasis will be placed on civilian PCIs.

An alarmingly high number of PCIs in children can be attributed to the accidental discharge of firearms. Of all reported PCIs, 70% occur in the home setting.¹⁵ An increasing number of American households, 38% in a recent study, keep loaded weapons, allegedly for security reasons.¹⁶ However, in a series of 450 patients with PCIs from Cook County Hospital (Chicago, Illinois), only six firearm incidents were related to criminal invasion of a home.¹⁷ Furthermore, a study from the state of Washington stated that only 23% of firearm-related deaths were considered justifiable defensive homicides.¹⁸ Although it is less frequent in children, the practice of Russian roulette falls between the categories of accidental discharge and suicide, tending toward suicide,¹⁹ often resulting in lethal damage to the brain (► Fig. 54.1). More than 75% of the guns used in suicide attempts and in unintentional injuries of 0- to 19-year-olds were stored in the residence of the victim, a relative, or a friend.²⁰

Firearms continue to be a popular method for committing suicide, especially among men. Although the elderly remain the fastest-growing group affected by suicide,²¹ there has been a threefold increase in childhood suicide during the past 40 years.²²⁻²⁴ The exact reasons for these increases are unknown; however, the situation likely reflects an increase in violence, poverty, and the availability of weapons.²⁵ Suicide is currently the third leading cause of death in young Americans, with a rate of 13.1 per 100,000.²⁵ The most common means of suicide in American youth age 15 to 19 years is firearms, accounting for 736 deaths (3.4 per 100,000).²⁶ Hispanic women have the highest incidence of failed attempts, whereas rural Caucasian men have the highest completion rate.^{25,27-29}

Of concern are two societal factors, often interconnected, that are affecting children at an increasing rate. The growth of criminal activities surrounding the illicit drug culture and the growth of gangs in urban, suburban, and even rural

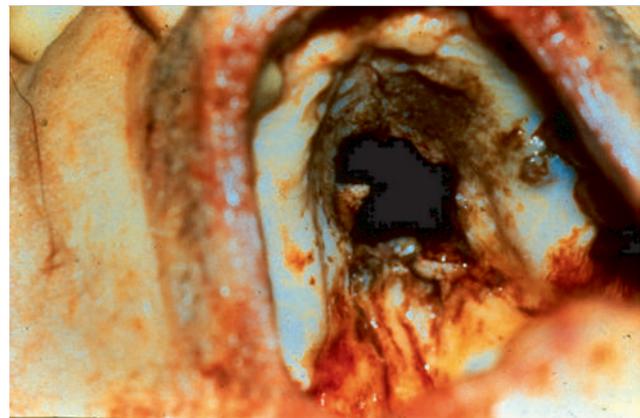

Fig. 54.1 Penetrating injury sustained during Russian roulette, with the bullet entering through the victim's palate.

Fig. 54.2 Photograph of gunshot injury and associated gang tattoo.

communities increasingly threaten the pediatric population (► Fig. 54.2 and ► Fig. 54.3).³⁰

Furthermore, the abundance and ready availability of powerful weapons being used with lethal intentions add to the toxicity of the situation. Homicide is the second leading cause of death in children in the United States after unintentional injuries, accounting for 11.4% of all deaths in 2011 and 12.1% of all deaths in 2010.³¹ The 8-year (1994 to 2002) homicide mortality rate per 100,000 persons was 26.4% for children aged 0 to 14 years.³² In 2009, firearms were involved in 84.5% of all homicides of people aged 15 to 19 years.²⁶ The fifth most common cause of death among patients aged 1 to 18 years reported in 2010 was firearm injury.³³ More than 11% of pediatric patients who were shot in 2011 did not survive.³⁴ In Tennessee, 47.8% of gunshot wound patients were between the ages of 14 and 25 years, whereas only 13.7% of the population of Tennessee falls within this age group.³⁵ In Harlem (New York City), a reported 40% of childhood gunshot victims were the intended targets, with 60% of their assailants children.³⁶ During 1991 in Los Angeles, California, 25% of all shooting victims, 412 of whom died, were younger than 18 years of age. Although traffic accidents are the leading cause of childhood deaths in the United States, gunshot homicides remain the leading cause of death among children in Los Angeles.³⁰

An exponential increase in gang-related activities can be seen throughout many areas of the country. The best data have been compiled in the city of Los Angeles. As of 2005, there were at least 1,108 identified gangs in Los Angeles County with 85,298 members, according to the CALGANG System of the California Department of Justice. Gang-related murders in Los Angeles increased from 271 in 1985 to 597 in 2001. In 1993, a study of 105 children treated for PCI at the LAC+USC Medical Center over an 8-year period found that 76% of the injuries were gang-related.³⁷ Likewise, Ordog et al³⁸ reported that 80% of the childhood victims in their series past the age of 10 years were involved in gang-related violence. Statistically, most shootings have involved African-American young men; however, homicides are in fact the second most frequent cause of death in girls of all ages.³⁹ Although gang-related and non-gang-related gunshot wounds show statistically significant differences in demographics and entrance sites, they do not differ in respect to survival and outcome.⁴⁰

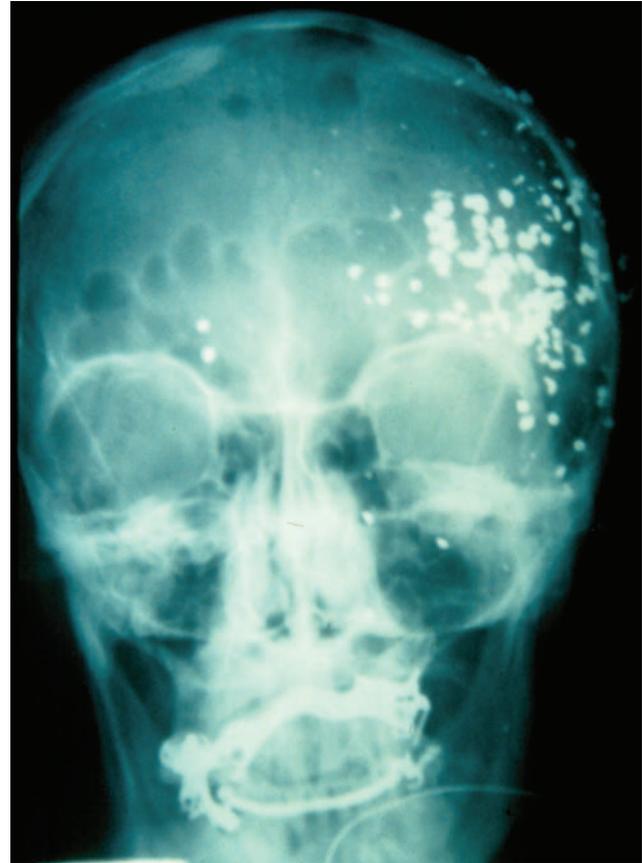

Fig. 54.3 Plain anteroposterior skull film of a 20-year-old man demonstrating diffuse extracranial and intracranial shrapnel. This resulted from a shotgun blast at approximately 20 ft.

While prevention of such devastating injuries is the overall goal, it seems drastic societal changes will be necessary to reverse the trend of gang-related childhood fatalities. In any case, neurosurgeons must be prepared to treat pediatric PCIs.

54.2 Clinical Presentation, Diagnostic Studies, and Early Treatment

The initial assessment and treatment of PCIs occur at the site of injury. An effective and expansive emergency medical system has been established in most communities in the United States; therefore, emergency medical technicians and paramedics generally provide initial care. Appropriate resuscitation and stabilization attempts combined with prompt transport to EDs have positively influenced outcomes.^{41,42} Through communication with initial emergency response teams, the neurosurgeon is often a participant in these activities and should be familiar with assessment and stabilization procedures at the early stages of treatment.

Immediate attention must be given to the fundamentals of airway, breathing, and circulation (ABCs). Furthermore, PCIs are not limited to the cranium and can often involve the face and

skull base. Obstruction of airways can be caused by blood, mucus, and posterior prolapse of the victim's tongue. Brainstem injury can cause alterations in breathing. If the patient's respiration is effective, an orally inserted airway protective device should be inserted under direct visualization. If ventilatory support is required, oral intubation should be performed. A short-acting, nondepolarizing neuromuscular blocking agent (e.g., vecuronium, 0.01 mg/kg every 15 to 30 minutes) and sedative agent (thiopental, 4 mg/kg, or midazolam, 0.07 mg/kg) may be administered to the semiconscious victim to minimize rises in intracranial pressure (ICP). Nasal intubation should be avoided because of the increased risks for raising ICP and for iatrogenic injury. Although the role of hyperventilation in acute management has not been clarified, the administration of 10 L of supplemental oxygen per minute at a rate of 24 breaths has been recommended.⁴³ Pulse oximetry and end-tidal carbon monoxide monitors are becoming standard equipment on ambulances and can be used to optimize patients' ventilatory status.

Despite the often dramatic appearance of PCIs, life-threatening hemorrhage is rare; local pressure is generally sufficient to control bleeding in the field. Saline-moistened gauze sponges should be used to cover wounds. Exposed impaling objects should be left intact. A rigid collar should be applied before transportation if the possibility of concurrent cervical injury exists. Although routinely carried by transport teams, corticosteroids are not beneficial. The acceptance of patients for interhospital transfer is another common situation encountered by neurosurgeons, especially those at regional trauma or referral centers. Although all of the above issues still apply, it is necessary to ascertain if nonneurosurgical injuries have been fully diagnosed and properly stabilized. Consultations with a general or trauma surgeon at one's home institution may be indicated; however, transfer should not be delayed to obtain diagnostic studies. Although availability has increased, it remains unclear if transport via helicopter or fixed-wing aircraft positively affects patient outcome.^{44,45} In fact, some studies indicate that the time for initial transport is inversely correlated with outcome, possibly because unstable patients with a worse prognosis are often transported more rapidly than stable ones.^{46,47}

Upon the patient's arrival at the neurosurgeon's institution, the first step is the collection and documentation of essential information. This includes vital signs, Glasgow Coma Scale (GCS) score, a basic general and neurologic examination with the patient fully unclothed to survey all body surfaces, and a description of visible injuries. The location, size, and appearance of all wounds should be recorded. Creating a photographic record is recommended.

Ongoing management of the airway and circulation is essential. Hypoventilation ($PCO_2 > 40$ mm Hg) and hypoxemia ($PO_2 < 80$ mm Hg) need be avoided, as well as excessive hyperventilation ($PCO_2 < 25$ mm Hg), which can adversely affect cerebral blood flow. An orogastric tube should be placed to decompress the stomach. A euvolemic state can be maintained by the judicious use of isotonic crystalloid fluids (normal saline) titrated to urinary output, accurately measured via a Foley catheter. Hemoglobin and hematocrit should be determined and type- and cross-matched blood obtained. An extremely low hematocrit can be caused by massive hemodilution via resuscitative efforts or by large blood loss, the latter resulting either from a laceration of a major vessel or from internal or external hemorrhage

at other locations. This can lead to sudden and unheralded cardiovascular collapse, mandating aggressive correction of hypovolemia and anemia. In the young infant, enough blood can be sequestered in the scalp or cranial vault to result in hypovolemic shock without obvious external blood loss. Insertion of a central venous catheter is indicated for the assessment of intravascular volume status in the hemorrhaging patient.

The management of raised ICP or lowered cerebral perfusion pressure (CPP) may be necessary, either empirically in patients with deteriorating neurologic status or objectively in patients with intracranial monitors in place. Although potentially lifesaving in a herniating patient, the effect of such management on outcome beyond the initial resuscitative period is yet to be fully established. Some adult studies report improved outcome when the blood pressure and ICP can be controlled to ensure a CPP above 70 mm Hg^{48,49} however, pediatric studies replicating these results are lacking. Pediatric studies have established a correlation between CPP below 40 mm Hg in patients younger than 10 years and high mortality rates.^{50,51} Appropriate measures may include mannitol (0.5 to 1 g/kg intravenously every 2 to 4 hours to a maximum serum osmolality of 310 mOsm/L), furosemide (0.5 to 1 g/kg every 1 to 2 hours), and boluses of 3% NaCl (2 to 5 mL/kg initially followed by 2 mL/kg every 6 hours) and pressor agents, such as dobutamine. Elevation of the patient's head may slow hemorrhage from wounds but may adversely lower the CPP.⁴³

Disseminated intravascular coagulation (DIC) can occur any time after significant cerebral injury as a consequence of the release of brain tissue thromboplastin and initiation of the coagulation/thrombolytic cascade. It is directly correlated with the amount of brain injury and likely happens as frequently in the pediatric population as in adults. The prothrombin time, partial thromboplastin time, level of fibrin degradation products, and platelet count should be followed serially to identify this form of consumptive coagulopathy. The replacement of appropriate blood components (fresh frozen plasma, cryoprecipitate, platelets) should be initiated to prevent uncontrollable hemorrhaging. Furthermore, DIC indicates a poor prognosis in the adult population⁵² and may be a similarly ominous sign for infants, having been shown to be a predicting factor in the Glasgow Outcome Scale score⁵³ and associated with poor outcome.⁵⁴

54.3 Diagnostic Imaging

Computed tomography (CT) of the head is strongly recommended to evaluate the patient with PCI.⁵⁵ In addition to axial views of bone and soft tissue, coronal sections may be useful in patients with skull base or high convexity involvement. In selected cases, plain films may help to delineate skull fractures and bullet fragments; however, the CT scout alone is generally sufficient (► Fig. 54.4). Routine magnetic resonance (MR) imaging is not generally recommended in the early evaluation period.⁵⁵ Serial 5-mm CT cuts should be obtained from the vertex to the foramen magnum, with windowing to image bone, blood, and brain. Rescanning at different gantry angles can be helpful if large metallic fragments create markedly distorted images.

Subgaleal hematomas, common among children with PCIs, may be responsible for a significant loss of circulating blood volume. Skull fracture patterns can be used to distinguish entry

Fig. 54.4 Axial computed tomographic scan showing extensive cerebral damage from the bullet.

and exit wounds and the paths of projectiles. Entry sites are characterized by small holes, in-driven fragments, and beveled edges; exit wounds tend to be larger and irregular. The paranasal sinus should be studied for the presence of air–fluid levels. Although extradural hematomas are rare in PCIs, their rapid identification and surgical removal offer improved survival rates compared with those of subdural hematomas and subarachnoid hemorrhages commonly associated with PCIs. On CT scans, cerebral contusions and parenchymal hematomas may appear bright, dark, or of mixed density based on the proportions of hemorrhage and edema. Isodense contusions occur with some frequency and are better imaged with MR imaging, if necessary. Potential findings also include intraventricular blood, shear injury (e.g., blood or edema along the corpus

callosum), obliteration of the basal cisterns, and loss of gyral patterns.

Follow-up CT is warranted in selected cases because of the possible delayed development of intracranial hematomas. One study reported the highest rate of intracranial hematomas at 3 to 8 hours after initial injury. The development of a hematoma or further cerebral edema can present as acute deterioration, and therapeutic intervention may be required. Ischemic injuries, such as bilateral hippocampal, cerebellar, or watershed distribution infarction, may be seen on later scans.

MR imaging may play a role in evaluating injuries in several situations. First, it may be useful to ascertain cerebral contusion and shear injuries in patients whose neurologic examination is worse than would be predicted by CT scans. Second, MR angiography may be used to screen for traumatic aneurysms; however, in many cases in which vascular injury is suspected, conventional cerebral angiography is recommended. CT angiography may be beneficial as well. Third, gadolinium-enhanced MR imaging is more effective than contrast-enhanced CT when it comes to detecting cerebritis or the early development of extra- or intracranial abscesses, and it may be indicated in the evaluation of the febrile patient. Last, MR imaging may be useful in evaluating injuries from penetrating wooden or other nonmagnetic objects.⁵⁵

Although MR imaging can be done safely in the majority of cases with retained metallic objects, neurosurgeons must exercise caution when ordering images. An *in vitro* and clinical study revealed that most bullets produced in the United States and shotgun pellets used in domestic and police situations are nonferromagnetic and can be exposed to contemporary MR imaging magnets (1.5-tesla range) without risk for rotational injury.⁵⁶ Another recent study has indicated that common, commercially available bullets manufactured in the United States are safe in MR imaging scanners up to 7 tesla; however, armor-piercing rounds with steel cores are not.⁵⁷ Additionally, a study focused on fragments resulting from combat and terrorist attacks found these artifacts to be safe at 1.5 tesla.⁵⁸ ▶ Table 54.1 summarizes the ferromagnetic properties illustrated in these studies. Almost all metallic objects will distort and degrade images and can reduce the diagnostic yield of a study. As

Table 54.1 Summary of the literature on the potential for rotational movement and image artifacts of metallic objects with magnetic resonance imaging

Object	Composition	Movement potential	Artifact potential ^a
Shrapnel (bombs and artillery shells) or zip gun	Steel, lead, or mixed	++ to +++	0 to +++
Bullets	Bronze projectile	0	+ to +++
	Lead projectile	0	++++
	Lead projectile; steel- or copper-jacketed	++	+++
	Steel core; copper-plated, steel-jacketed	++	+++
Shotgun ammunition	Lead shot	0	+
	Steel shot	+	+
Pneumatic gun ammunition/BBs	Steel pellets	+	+

^aArtifact potential rated from 0 (least) to ++++ (most).

described in the ophthalmology literature, and of particular relevance to the pediatric neurosurgeon, BBs and pellets fired from many pneumatic weapons are generally made of steel and have the potential to move in strong magnetic fields.⁵⁹ The best approach is to have an expert, such as a police officer, examine the weapon, spent casings, unfired ammunition, or any relevant evidence retrieved from the patient to determine the composition of the projectile. If the composition of the projectile cannot be confirmed, the neurosurgeon must weigh the benefits of MR imaging against the potential for injury to neural or vascular structures if the object moves during imaging.

Although useful, prognostication based on radiographic imaging is imprecise. Without an initial GCS score, no single radiographic finding can be independently predictive of outcome.⁶⁰ Still, several observations have been noted, including elevated mortality rates with multiple-lobe,⁶¹ bihemispheric,^{62,63} multipolar,⁶⁴ and transventricular injuries^{62,64,65} (► Fig. 54.5), as well as subarachnoid hemorrhage,^{66,67} intraventricular hemorrhage,⁶⁸ intracerebral hematomas,⁶² and basal cistern effacement.⁶⁹ Furthermore, poor outcome associated with bihemispheric injuries has been reported in two groups, and occipital entrance wounds are usually fatal.^{70,71}

54.4 Surgical Treatment

Although most neurosurgeons would decline to operate on a patient without neurologic function, the choice for surgical intervention can be complex. When a low GCS score^{4,72,73} is combined with an ominous sign, such as nonreactive pupils or refractory hypotension, the decision to withhold surgery seems warranted.⁷⁴ Upon review of the neurosurgical literature, the benefit of operating on patients with post-resuscitative GCS scores of 3 to 5 at the time of presentation remains unclear because of a mortality rate higher than 80% and a rate of poor outcomes that approaches 100%, with significant yet infrequent exceptions.⁷⁵ The issue becomes more complex in the pediatric population because predictive pediatric models are nonexistent. Furthermore, the emotional overlay of tragedy is often compounded when children are involved, putting an overwhelming burden on parents when it comes to decision

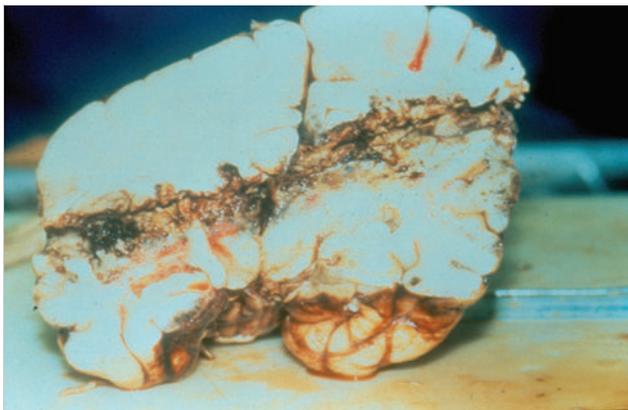

Fig. 54.5 Autopsy brain specimen of a through-and-through penetrating cerebrocranial injury with ventricular compromise following discharge of a rifle at short range. Note the discoloration of the tract and multiple areas of cavitation.

making. Under these circumstances, decisions must be individualized and based on an analysis of the clinical and radiologic factors, as well as discussion with colleagues and family members. In light of these complexities, neurosurgeons should generally err on the side of aggressive treatment with pediatric patients who have PCIs.

Kaufman⁷⁴ has suggested three primary reasons to operate: (1) to remove foreign objects (e.g., missile fragments, bone) to prevent secondary complications, such as infection, posttraumatic aneurysms, and seizures; (2) to remove necrotic brain to prevent further hemorrhage, edema, and scar formation; and (3) to eliminate mass effect, especially that associated with hematomas, on viable brain. Other indications for operative management include debridement and closure of scalp wounds, repair of vascular injuries, and placement of a device to monitor ICP. Unfortunately, the data are insufficient to show the impact of these procedures on clinical outcome with accuracy. In any case, the current understanding of traumatic pathophysiology and standard of care would suggest that such procedures are often appropriate.⁷⁶

Certain issues warrant further discussion. First, the timing of surgery is an important consideration. Certainly, hemodynamically unstable, multiply traumatized patients and those with DIC must be stabilized to avoid high operative morbidity and mortality rates. Although early and aggressive debridement has been the standard treatment in military PCIs,^{77,78} prompt but locally confined debridement is considered sufficient in civilian PCIs.^{74,79} For patients presenting more than 24 hours after injury, more aggressive debridement would be indicated because of an increased risk for infection. Scalp and skull wounds should always be explored for necrotic skin, hair, and bone fragments that can be safely removed. Dural and vascular injuries should be repaired and copiously irrigated. No evidence indicates that extensive parenchymal debridement or the removal of deeply penetrating bullet fragments or bone prevents infection. Two studies suggest that retained fragments may increase the incidence of late seizure development and traumatic aneurysm formation^{11,12}; however, this must be weighed against the risk for further neurologic injury during operative manipulation. Most neurosurgeons recommend the prompt removal of “significant” hematomas; however, the minimal volume has not been established.⁷⁴ Despite recommendations for a more aggressive approach with posterior fossa wounds, because of the small volume of this compartment and poor tolerance of compression, two series have found that pediatric patients with occipital entry wounds have poor outcomes despite surgical intervention.^{70,71}

In most cases, standard craniotomy techniques should be applied. An important consideration in the design of the scalp flap is the excision of contaminated and heavily damaged soft tissue. Bone from the scalp and entrance sites can be removed if small local debridement is anticipated. Although some authors have advocated osteoplastic flaps, no reduction of the infection rate has been shown with this technique.^{52,80} Debridement of the parenchyma should be performed with the use of copious isotonic fluid irrigation and controlled suction. The primary goals are to remove large, easily accessible foreign objects at the entry and exit sites, remove hematomas, and control hemorrhage. The insertion of small-diameter red rubber catheters followed by irrigation to assist with the removal of deeper hematomas is

rarely warranted. If necessary, a hemostatic agent such as peroxide or oxidized regenerated cellulose can be employed. Intraoperative ultrasound can be effective in localizing bone, metal, and clots. Objects as small as 1 mm have been detected when a 7.5-Hz probe was used. (However, deeply embedded objects should probably be left in place, regardless of size.⁷⁴) Repair of a transgressed dural venous sinus is indicated if there is active hemorrhage, but the bleeding can often be controlled with tamponade. The anterior sagittal sinus may be ligated as far posteriorly as the entrance of the first major cortical vein.

The dura mater may be closed primarily or reapproximated. One recent military series reported a reduction in the incidence of cerebrospinal fluid (CSF) leaks and infectious complications with dural closure⁸¹; another study stressed watertight closure of wounds (with a graft if necessary) and closure of the scalp in layers.⁷⁷ In general, if the wound can be debrided and irrigated and the scalp can be closed to prevent external leakage of CSF, then a dura mater approximation with absorbable suture material should be sufficient. The application of fibrin glue to the suture line can be considered because it is safely used in non-trauma situations to effectively prevent CSF leaks.⁵² When large defects are closed, suitable dural substitutes include vascularized pericranium, temporalis fascia, and fascia lata, although one author found that the latter did not prevent infection.⁸² Silastic (Dow Corning, Midland, MI) and other nonabsorbable materials should be avoided because they have been implicated in infections and remote hemorrhages.⁸³ In many cases, dural defects can be managed with the application of a large piece of gelatin film between the exposed dural edges and the cortical surface plus the placement of oxidized cellulose on the external surface of the exposed dura mater.

Cleansed bone should be replaced unless highly contaminated. Although wire mesh can be safely used, acrylics should be avoided because of their tendency to harbor bacteria in their porous matrix. In one series of patients undergoing elective cranioplasty with methylmethacrylate, 22% developed infections if the mucosa of the frontal sinus was exposed.⁸⁴ A delay of 6 to 12 months has been recommended if an extensive cranioplasty is required.⁷⁵

If possible, the scalp should be closed in two layers, with absorbable sutures approximating the galea and a second suture line to appose the skin edges. A rotational flap may be necessary in cases of large defects. The prophylactic insertion of a lumbar drain to promote sealing of dural tears is not indicated; however, this method may be employed if a CSF leak develops.

The risk for infection and CSF leak is increased in patients who sustain transorofacial wounds, and thus special consideration is necessary.⁷⁴ The assistance of plastic, head and neck, and/or oral surgeons may be warranted. Aggressive debridement of all cavities communicating with the intracranial compartment, exenteration of the frontal sinus mucosa, and dural repair are the standard treatments. Also of importance in these cases is perioperative broad-spectrum antibiotic coverage for gram-positive, gram-negative, and anaerobic organisms.

The insertion of an ICP monitor at the time of operation should be considered, based on the extent of the injury. Delayed edema occurs regularly in patients with PCIs, and rapid increases in the ICP may indicate the onset of progressive cerebral edema, hydrocephalus, or hematoma formation. Although ICP monitoring is indicated for all patients with severe closed head

injuries,^{41,42} fewer than half of surveyed neurosurgeons reported routinely monitoring the ICP of patients with severe PCIs.⁸⁵ Ventriculostomies can provide an advantage over extraventricular monitoring systems by allowing CSF drainage for the management of increased ICP or impaired CSF circulation. The efficacy of measures to lower the ICP in both adult and pediatric PCI victims is yet to be determined.

54.5 Complications

54.5.1 Infections

The specific rate of extracranial and intracranial infections in children with PCIs has not been reported; however, broader studies have shown high infection rates ranging from 25 to 50%.^{86,87} Some of the possible infectious complications include scalp cellulitis and abscess formation, osteomyelitis, epidural and subdural empyemas, meningitis, ventriculitis, cerebritis, and brain abscess. Based on studies of the general population, several factors are apparent when infectious complications are treated. First, the speed of the penetrating object is important. Although generally seen in a military setting, PCIs from high-velocity bullets tend to have a lower rate of infection, in the range of 5 to 7%.^{77,79,80,82,85,88-90} A study of low-velocity injuries in a pediatric population showed an alarmingly high rate (43%) of infectious complications.⁶ In the report of 54 cases, 14 patients developed brain abscesses, 6 meningitis, 2 scalp infections, and 1 calvarial osteitis. In almost all of the cases, infection was caused by *Staphylococcus aureus*. Second, there is a positive correlation between the infection rate and the level of contamination as well as delay in treatment. In-driven hair, scalp, and superficial bone in volumes larger than 1 mL are significant risk factors for infectious complications.^{89,91} Third, concomitant injuries (e.g., skull fractures with CSF leakage, paranasal sinus fractures that communicate intracranially, and oral injuries) have been historically associated with increased infectious complications. Fourth, the composition of the penetrating object correlates with infection rates, especially in instances in which foreign material is retained. Although most bullet fragments are hot, inert metals, many organic materials, especially wood, can harbor many pathogenic microorganisms. In a study of 42 patients (80% of them pediatric patients), almost 50% developed an infectious complication.⁸⁷ Finally, surgical exploration and debridement play an important role in infectious complications. Although the removal of gross superficial contamination is important, the removal of deeply embedded bone and projectile fragments does not decrease the incidence of infection. Several authors reported good results with little or no retrieval of foreign objects.^{63,88,92} Some recommend serial CT if a minimalist surgical approach has been taken; however, careful clinical surveillance is generally sufficient on a long-term basis.

Prophylactic antibiotics do not ensure the avoidance of infection, nor has the role of prophylaxis been fully clarified. Many authors support the need for the early administration of broad-spectrum antibiotics^{65,68,93} however, others recommend that intraoperative cultures be obtained and that antibiotics be administered only when the cultures are positive. One study reported a 10% incidence of meningitis and wound infection despite the use of antibiotic coverage.⁹⁴ A variety of appropriate antibiotics are available; these range from single, semiselective

agents like cefazolin to third-generation cephalosporins plus antipseudomonal and anaerobic agents. Antimicrobial therapy is given intravenously for 5 to 14 days with or without additional oral agents for a similar period. To reduce the rate of bacterial resistance as well as cost, the nature of the contamination should be considered when an antibiotic is chosen. We recommend that a 7- to 10-day course of cefazolin be administered to minimally contaminated patients, and that a 7- to 14-day course of ampicillin, gentamicin (or third-generation cephalosporin), and metronidazole be given to heavily contaminated patients. In the presence of methicillin-resistant *S. aureus*, vancomycin should be used instead of ampicillin. Furthermore, the debridement site should be cultured intraoperatively, as one study found a 76% correlation between wound cultures and brain abscesses in patients in whom this complication developed.⁹¹

Evaluation for infection should definitely be undertaken in the case of patients with PCIs who have fever, a change in mental status, or new focal neurologic deficits. Although laboratory studies, such as white blood cell count, C-reactive protein, and erythrocyte sedimentation rate, can be correlative, obtaining an imaging study is a priority. CT offers the benefits of speed and affordability, but contrast MR imaging may have better diagnostic abilities. MR imaging can discern soft tissue, bone, and brain infections in their earliest stages. T1-weighted images will show sulcal effacement with mass effect, whereas T2-weighted images show increased signal of cerebral edema associated with early cerebritis.⁹⁵ It should be noted that during attempts to distinguish between an infectious process and simple posttraumatic cytotoxic edema, paramagnetic contrast enhancement will generally be present in developing cerebritis and abscesses, although exceptions have been found early in the process.⁹⁶ When imaging is ambiguous, empiric antibiotic coverage should be considered and a study repeated 7 to 10 days later to determine if a characteristic ring-enhancing lesion has developed. In patients with meningitis, fine-cut CT, CT cisternography, or MR imaging of the skull base can help evaluate potential sites of CSF leakage. Appropriate medical and/or surgical intervention should be undertaken as directed by the imaging and is discussed elsewhere.

54.5.2 Seizures

Cases of seizure, including early-onset seizure (less than a week), late-onset seizure (after a week), and epilepsy (chronic seizure disorder), are not well documented in children with PCIs. If one considers the nature of the central nervous system in pediatric patients with closed head injuries, which has been studied, one would expect the rate of seizures to be high after PCIs.⁹⁷ In series of adults with PCIs, the incidence of early seizures ranged from 1 to more than 30%, considerably higher than the incidence in patients with closed head trauma, and the incidence of late seizures has been reported to be as high as 54%.⁹⁸ In most cases, late seizures occur four to eight times more often than early seizures, implying that the two conditions may have a different pathogenesis.⁹⁶ The data, however, are confounded by the variable administration of prophylactic anticonvulsant medications.^{63,93,97-99}

To better understand the incidence of seizures in the pediatric population with PCIs, it is necessary to evaluate the literature on traumatic brain injury that is restricted to this age group. Despite the fact that the vast majority of patients sustained closed head injuries, several studies have reported incidence rates of early seizures of 5 to 15%.¹⁰⁰⁻¹⁰⁹ One series of patients with low-velocity PCIs reported a 17% incidence of early seizures.⁶ The long-term follow-up of pediatric patients with PCIs is poor; likewise, the incidence rates of late seizures and epilepsy have been reported infrequently. However, larger series with small numbers of children suggest that late seizures and epilepsy are more frequent than early seizures.

Some authors have attempted to identify the clinical characteristics that are predictive of posttraumatic seizures in children following PCI.¹⁰³⁻¹⁰⁶ Possible predictors include a GCS score of 3 to 8, diffuse cerebral edema, acute subdural hematoma, prolonged loss of consciousness, and depressed skull fracture. The strongest indicator is a persistently low GCS score, with up to 53% of children in this category manifesting early seizures. However, in one retrospective analysis of seven children with PCI and a low GCS score, none manifested early seizure activity.¹⁰⁶ Overall, the identification of predictive factors for posttraumatic seizures in the pediatric population remains incomplete.

Although earlier literature suggested no benefit,¹⁰⁷⁻¹¹⁰ prospective and retrospective studies including both adults and children generally affirm the efficacy of phenytoin for the prevention of seizures in the first week after injury.^{98,102,106,111,112} In one survey, 84% of neurosurgeons reported the routine use of prophylactic anticonvulsant medication for patients with severe head injuries.⁸⁴ In a prospective adult trial, the reduction in the rate of seizures was nearly fourfold, from 14% in the placebo group to 4% in the treated group. Still, in studies, the rates of late seizures and epilepsy have not been reduced, suggesting that prophylaxis is not effective on a long-term basis.

Overall, based on a summary of the literature, prophylactic anticonvulsants in the first week after injury would be recommended for most pediatric patients with PCIs. Seizure-related increases in ICP and other secondary injuries may then be reduced. Withholding prophylactic anticonvulsant medications from children with minor injuries and high GCS scores would also be an acceptable protocol. After the first week of hospitalization, the decision to continue anticonvulsants should be made on an individual basis. However, the occurrence of early seizures does not bode well for patients, who remain at high risk for the development of epilepsy requiring long-term anticonvulsant medications.¹⁰¹

Although phenytoin is the most commonly used anticonvulsant medication in published series, other medications should be considered. Phenytoin, when administered orally or intravenously, is highly effective and generally safe. For very young children, or those who may need extended therapy, phenobarbital is a good choice; however, it can cause adverse behavioral changes. During the acute period, intravenous administration is crucial, especially in the case of infants, who have poor enteral absorption of many anticonvulsant medications. If intravenous access is not possible, the rectal route is acceptable for phenytoin and the benzodiazepines; hospital pharmacies can generally

prepare the medications quickly if needed. The key factors in safety and effectiveness are administration of the loading dose and surveillance with frequent serum levels. Assessment of the levels is necessary every 2 to 3 days, especially because significant fluctuations in phenytoin levels are observed in severely injured patients with unstable serum protein levels.¹¹³

Discontinuation may be possible after 3 to 6 months if the patient remains seizure-free; however, little guidance has been found in the literature regarding this matter. If seizures have developed in a child more than a week after injury, anticonvulsant medication should be continued for at least 2 years, at which point the recurrence rate is still expected to be high. Furthermore, over time, the clinical and electroencephalographic (EEG) manifestations may change, with one study showing an evolution from early generalized to later focal types based on the site of injury.⁹⁷ The treatment of focal seizures, which can be difficult to control, may require the help of a pediatric neurologist. Before anticonvulsant medications are withdrawn, an EEG is often sensible.

54.5.3 Traumatic Aneurysm Formation

The formation of cerebral aneurysms after PCIs is an uncommon yet well-known event, occurring in up to 5% of patients with PCIs in all age groups.^{11,12} Although the incidence in pediatric PCIs is unknown, some suggest it is more common among the pediatric population than in adults.¹¹⁴ A study at Children's Hospital Los Angeles found 7 cases of pediatric traumatic aneurysm over a 17-year period, one of which was secondary to PCI.¹¹⁴ In a military series from Lebanon, 13 of 40 victims in whom aneurysms developed after injury to the head from high-velocity projectiles were 18 years of age or younger.^{11,12} Low-velocity injuries can also cause aneurysms, as shown in a study of 54 patients, 2 of whom developed traumatic aneurysms after impalement or pellet wounds.⁶

Pseudoaneurysms are the most common lesions and are thought to result from damage of the arterial adventitia and media within hours or a few days after injury. Pseudoaneurysms can evolve along the length of any damaged cerebral artery, including the intracavernous carotid, can involute or enlarge unpredictably, and may hemorrhage early or many years later, with potentially devastating outcomes. Behavioral and neurologic changes have been linked to these lesions.¹¹⁴ Acknowledged predictors for the development of traumatic aneurysms include: (1) course of a projectile or bone fragment through areas of dense vasculature or the skull base, (2) impalement of an object through the above-mentioned regions, (3) trans-hemispheric passage of a projectile, (4) large intracerebral hematomas associated with an entrance wound, (5) multiple fragments with scattered paths, and (6) heavy arterial bleeding during initial debridement.^{11,12,67} Cerebral angiography at 7 to 10 days after injury should be seriously considered in the presence of any of the above-mentioned factors. Because immediate surgical treatment is considered safe and effectively eliminates the risk for hemorrhage, aneurysms of any size should be clipped, excised, or wrapped. Similarly, abnormal vessels should be treated at the time of initial debridement.

54.5.4 Wandering Fragments and Lead Poisoning

Several case reports exist of wandering metallic fragments along the neuraxis. Reports have been made of the migration of shotgun and air rifle pellets into the anterior and posterior cerebral circulation through both intra- and extracranial wounds, creating cerebral infarctions.¹¹⁵ One author describes cerebral softening, leading to the migration of large bullet fragments. The high specific gravity of metal compared with that of brain, and the sink action of the CSF flowing through the cerebral ventricles, may contribute to this condition.¹¹⁶ Both fatal migration into the brainstem and the development of hydrocephalus when fragments occlude the cerebral aqueduct have been documented.¹¹⁷⁻¹¹⁹

Another uncommon complication of retained metal fragments is lead poisoning.¹²⁰ Several weaknesses in the analysis of the data for this topic have been reviewed.¹²⁰ Well-documented cases exist of victims with an extensive amount of shotgun pellet throughout the body. Unfortunately, urine lead levels may be unreliable. Furthermore, the latent period of lead poisoning can vary from 6 months to many years, and the signs and symptoms are generally erratic and indistinct, including weakness, dizziness, headache, abdominal pain, constipation, and vomiting. Because of the decline in the use of lead in ammunition, the already infrequent problem of lead poisoning should wane even further.

Considering the above factors, if surgical removal is contraindicated because of potentially worsening neurologic injury, retained fragments near ventricles or major cerebral vessels should receive diligent surveillance. An immediate radiographic evaluation (either CT or cerebral angiography) should be undertaken at the onset of focal deficits or a deterioration in clinical status. Because of the potential for secondary hydrocephalus or neurologic injury, most intraventricular fragments should be removed. Locating the object radiographically in the operating room, before surgical exposure, is recommended because large bullets can move with positioning.¹¹⁶ When there are large amounts of retained lead fragments, the patient should be monitored clinically for signs or symptoms of lead poisoning. In the case of diagnostic evaluation and/or chelation, consultation with a hematologist or toxicologist is recommended.

54.6 Survival and Prognostic Factors

Any discussion of outcomes in children with PCIs is plagued by problems that include early and high mortality rates compounded by the overall small number of victims, so that predictive analysis is difficult. As mentioned earlier, withholding care from a patient presenting with a GCS of 3 and fixed pupils after initial resuscitative efforts seems wise. Likewise, one series¹²¹ noted that no pediatric patient with a traumatic brain injury and concomitant protracted anoxic insult regained useful consciousness, suggesting that supportive care alone is appropriate in this group. Aggressive neurosurgical management should be

pursued in patients with GCS scores of 12 to 15 and limited parenchymal injuries because they often have excellent functional recoveries.

The dilemma most commonly associated with PCIs is the management of patients with moderate to severe injuries. Many seriously injured children can survive with aggressive surgery; however, quality of life is often greatly compromised. One series of patients presenting with GCS scores of 3 to 5 reported that 99% of nonaggressively treated patients died. Although the majority of patients who underwent surgery survived, 90% had severe long-term disabilities, with families and physicians often questioning the good of the intervention.¹²² Other series report a multitude of lasting complications, including persistent vegetative state, functional dependency, blindness, paralysis, seizure disorder, and profound neuropsychological alterations affecting memory, language, and behavior.^{71,123,124} An analysis of war veterans who were young adults at the time they sustained PCIs found a substantial decrease in life expectancy correlated with posttraumatic seizure disorder in comparison with the general population.¹²⁵

Most studies of children with craniocerebral trauma focus on those with closed head injuries, and one must be careful when applying their findings to children with PCIs. Regardless, studies of outcome in children with severe craniocerebral trauma create a disconcerting image. One study found that long-term survival is much more common in children with prolonged periods of unconsciousness or vegetative state than in adults.¹²¹ At least one study has connected GCS score with neurobehavioral outcome, showing that patients with an initial score of 5 or less, as well as those who had a slow improvement in their GCS score, demonstrated substantial long-term impairments in intellect, adaptive problem solving, memory, academic performance, motor performance, and psychomotor problem solving.¹²⁶ Still, even children with less severe injuries have been found to have significant limitations in physical health and behavioral problems and can require special educational intervention in comparison with the general pediatric population. Contrary to the belief that children fare better than adults, the analysis of Kaufman et al¹²³ of a small group of patients with PCIs found similar incidences of problems regardless of age, including functional disability, need for special education, and extreme emotional lability. Generally, if improvement occurs in moderately or severely injured children, it usually plateaus after the first year following injury.^{121–127} In some children with less severe injuries, the harmful consequences for cognition, behavior, and psychosocial adjustment may not be fully realized until adulthood.^{128,129} One study found that only 23% of adults who sustained traumatic brain injury in their preschool years were able to work, and only 36% lived independently in the home setting.¹²⁹ Another study of PCIs, focusing on patients presenting with GCS scores of 3 to 8, concluded that although mortality rates are high, patients who survive to receive inpatient rehabilitation can achieve functional improvement.¹²⁷ Long-term focal deficits can often be reliably predicted based on the location of an injury,¹³⁰ but the heterogeneity of the PCI population makes further predictions and analysis quite challenging.

Pearls

- Early involvement by the neurosurgeon in the initial assessment and management is essential for timely and appropriate decision making. Children presenting with GCS scores of 3 to 4 or with posterior fossa entrance sites are likely to die and should be managed accordingly.
- Surgical intervention should be individualized according to the site and extent of injury. Limited debridement and careful wound closure are often sufficient. Further evaluation (e.g., angiography) and deeper exploration may be indicated when large foreign bodies are in juxtaposition with the ventricles or major cerebral vessels.
- Short courses of prophylactic antibiotics are generally indicated, especially in patients with low-velocity injuries, which have a high risk for infectious complications.
- Prophylactic anticonvulsant medications are generally indicated during the first week after injury. Beyond that period, the neurosurgeon should use discretion about prolonged administration, realizing that the prevention of late seizure activity has never been demonstrated. The development of late seizures, however, generally heralds the onset of a chronic seizure disorder that will require long-term anticonvulsant medication.
- The neurosurgeon should remain vigilant for the development of delayed complications. These include brain abscess and traumatic aneurysm formation, wandering intracranial fragments, and lead poisoning.
- Residual and delayed neurologic and functional deficits are common, even though considerable improvement may be observed in the first year after injury.

55 Intracranial and Extracranial Hematomas in Children

Anthony Figaji

There are many causes of intracranial and extracranial hematomas in children; this chapter focuses on the most common and the most relevant to neurosurgical intervention.

55.1 Basic Pathologic and Pathophysiologic Considerations

Intracranial hematomas present a major risk for death and disability because they increase intracranial pressure (ICP) and displace brain. The volume within the cranial compartment is fixed (Monro-Kellie hypothesis); therefore, any increase in one of the principal components (brain, blood, cerebrospinal fluid [CSF]), or the addition of another component (e.g., hematoma) must be compensated for by a change in one of the other components—initially, CSF and venous blood. If this compensation is inadequate or exhausted, ICP increases and brain shift occurs, leading to global or focal ischemia, brain distortion, focal deficits, and decreased consciousness. Of great clinical importance is the nonlinear relationship between increased intracranial volume and pressure. When the brain is able to compensate for changes in volume, there is little change in ICP; however, once the compensatory capacity, or compliance, of the intracranial space is exhausted, ICP increases dramatically with any further small increase in volume. Therefore, an awake patient with an intracranial hematoma remains at risk for sudden deterioration and should be treated with caution and care, even when he or she is neurologically intact. Open fontanels and sutures in infants and young children offer limited protection against an acute rise in pressure.

The risk for an intracranial hematoma depends on the etiology, location, speed of accumulation, and eventual size. Hematomas of arterial origin accumulate most rapidly. Posterior fossa hematomas are particularly dangerous because of the relatively contained infratentorial space, resultant pressure against the brainstem, and occlusion of the fourth ventricle leading to hydrocephalus. The condition of the brain is important—large intraparenchymal contusions and/or brain swelling may lower the threshold for removing relatively small extra-axial hematomas. Conversely, if a lesion has minimal mass effect in a patient who is systemically unstable (e.g., a patient with polytrauma), is medically unwell (e.g., a patient with cardiac disease), or has a coagulopathy, an initial conservative approach may be more prudent. Acute evaluation must also consider the potential dynamic element; very early imaging may underestimate the enlarging hematoma, and the initial clinical examination must be supported by ongoing and close neurologic monitoring to detect any delayed deterioration in a timely manner.

55.2 Imaging

Plain skull radiographs rarely contribute to the initial assessment; although linear fractures may indicate an underlying hematoma, clinically important intracranial pathology in trauma may be present with no fracture, and therefore plain skull

radiographs are not reliable indicators for further imaging. The exceptions are suspected nonaccidental injury and the follow-up of potential growing skull fractures. Computed tomography (CT) of the head is the primary imaging modality in most circumstances. Some institutions prefer magnetic resonance (MR) imaging, even in emergencies, but this requires controlled sedation or general anesthesia in younger children, and it may not be logistically feasible in an emergency setting. There are clear benefits of MR imaging, though, particularly for nontraumatic hematomas, the underlying cause of which can be more thoroughly investigated. The characteristics of blood products on MR imaging depend on the MR imaging sequence and time after bleed. In many ways, head CT is simpler and quicker, and it remains the standard for emergency evaluation. However, concerns about the radiation dose delivered to the developing brain are growing.^{1,2}

The most important imaging characteristics to assess are the following: hematoma size, regional location (left or right, posterior fossa or supratentorial); layered location (epidural, subdural, parenchymal, subarachnoid/intraventricular); local mass effect and distortion of the brain; comorbid brain swelling or hydrocephalus; and any additional pathology associated with the cause of the hematoma. The size of the hematoma can be estimated by the ABC/2 rule: *A* measures the longest diameter of the hematoma, *B* measures the diameter perpendicular to the *A* line, and *C* measures the number of slices over which the hematoma is visible multiplied by the slice thickness in centimeters. If the image slice contains 75% or more of the hematoma volume at its largest, it is counted as 1 full slice; if 25 to 75%, it is counted as 0.5 slice; if less than 25%, it is not counted. The three measurements are then multiplied and divided by 2 to derive a volume in milliliters.³ The rule works best with intraparenchymal hematomas but can be adapted for extra-axial hematomas. Midline shift is measured on axial CT at the third ventricle, septum pellucidum, or pineal gland; it may be greater than the width of the hematoma when hemispheric brain swelling is present. Hematomas are hyperdense on head CT but may be isodense if hyperacute (as on a very early scan), and they lose their density over time. Subdural isodense lesions may be difficult to appreciate before the typical hypodensity of chronic hematomas develops.

55.3 Extracranial Hematomas

Extracranial hematomas seldom require surgery. They typically occur after some form of trauma.

55.3.1 Childhood Posttraumatic Scalp Hematomas

Scalp hematomas are common after childhood trauma and seldom are of any surgical importance other than indicating the severity and location of the trauma. They may overlie a skull fracture. These hematomas may be large because of the vascularity of the scalp and easy accumulation. This is of particular

importance in infants, in whom the blood lost in the hematoma may cause a significant drop in the hemoglobin level. Scalp hematomas sometimes increase in size as they resolve and the clot liquefies. Rarely, they may become secondarily infected. “Raccoon eyes” and the Battle sign (mastoid bruising) may indicate a fracture of the base of the skull.

55.3.2 Neonatal Subgaleal (Subaponeurotic) Hemorrhage

Subgaleal (subaponeurotic) hemorrhage can be life-threatening in neonates because of the wide potential space in which the clot can spread. Unlike the cephalohematoma, it is not limited by suture lines, so that ongoing bleeding may lead to severe anemia and hypotension; therefore, mortality is high. It presents with a diffuse scalp swelling or fluctuant mass, crosses suture lines, and shifts when the child's head is repositioned. It may be associated with a skull fracture or with rupture of an interosseous synchondrosis or emissary veins between the subdural and subgaleal spaces.⁴ Instrumented delivery is a risk factor. Occasionally, surgery may be required to control the bleeding vessels.

55.3.3 Cephalohematoma

Cephalohematomas are localized subperiosteal clots caused by birth trauma, more often associated with instrumented delivery. The hematoma is limited by the adherence of the periosteum at skull sutures and most commonly occurs parietally, sometimes bilaterally. Occasionally, it is significant enough in size to decrease the infant's hemoglobin level, but this is rare; most are asymptomatic and resolve spontaneously over a few weeks. Cephalohematomas sometimes enlarge and/or calcify over time, leaving an unsightly bump in the parietal region. This can be corrected at a later age. Uncommonly, they may become infected, leading to meningitis or osteomyelitis. This rarely requires a diagnostic tap—possibly if there is an increase in size, the development of erythema and/or fluctuance, or delayed resolution or relapse of clinical signs of infection.⁵ Sometimes, there is an associated epidural hematoma at the same site that is in communication with the extracranial lesion. Rarely, a traumatic cephalohematoma may occur in an older child. A cavernous hemangioma of the skull may occasionally look like a cephalohematoma (► Fig. 55.1).

55.4 Intracranial Hematomas

Intracranial hematomas may be traumatic or spontaneous. Many of the principles that apply to the former apply equally to the latter.

55.4.1 Traumatic Hematomas

Basic Surgical Principles

The removal of an intracranial hematoma in trauma usually constitutes an emergency. The patient is transferred to the operating room after resuscitation and head CT. The anesthesiologist must prepare for ongoing resuscitation and potential

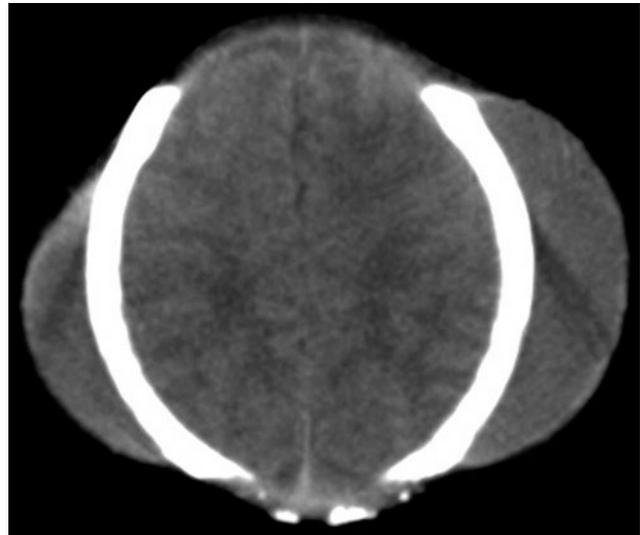

Fig. 55.1 Cephalohematoma. Computed tomographic scan of the head showing the typical appearance of bilateral cephalohematomas.

hemorrhage; large-bore intravenous access and blood cross-match may be needed; clotting must be checked. The head of the operating table is elevated to approximately 20 degrees. Hypertonic saline or mannitol may be used to decrease ICP during preparation for the craniotomy, as may *temporary* mild hyperventilation, while a high inspired fraction of oxygen is maintained. Blood pressure is aggressively maintained, and at no point should the patient be allowed to become even slightly hypotensive. The patient is positioned and the skin flap is planned according to the type of craniotomy planned.

As a general principle, the skin incision and corresponding bone flap should be large enough to allow maximal decompression and the control of bleeding points. For hematomas over the convexity, a large trauma flap (question mark or reverse question mark) incision is performed, for frontal lesions a bifrontal skin incision is made, and for posterior fossa lesions a linear midline or paramedian incision is used. For localized convexity epidural hematomas, a linear incision is sometimes sufficient. For trauma flaps, always ensure that the base of the flap is larger than the length to ensure viability. If the patient's condition is deteriorating rapidly, priority is given to temporal decompression to allow maximal space at the level of the tentorial hiatus before the rest of the craniotomy is completed. Hemostats are used to minimize bleeding from the scalp edges. When turning the scalp flap, take care to not create a sharp fold that reduces blood flow to the flap, especially in very young children. When the bone flap is created, the craniotome is angled to create a bevel that improves contact of the flap when it is replaced. If the dura needs to be opened, ensure that brain swelling has been maximally controlled first (see below). After the hematoma is out, spend time ensuring adequate hemostasis to avoid returning to the operating room to evacuate a re-collection. A subgaleal drain may be used postoperatively (and only for a short period) but should never be a substitute for poor hemostasis. Further details about specific hematomas are discussed in their relevant sections below.

Whether the bone flap is replaced primarily after evacuation of acute subdural or intraparenchymal hematomas depends on

the circumstances. If there is substantial brain swelling or increased ICP (with a monitor in situ), it may be safer to leave the bone flap out so that brain swelling may be controlled in the intensive care unit. In this case, the dura may be enlarged with a pericranial patch. These decisions should be individualized. If the bone is left out, it should be kept in a bone freezer in sterile conditions, or in an abdominal pocket, and replaced as soon as brain swelling has settled (within 4 to 6 weeks if possible). If there are no concerns after the hematoma is evacuated, the bone is replaced.

In general, a lower threshold is used for the evacuation of posterior fossa hematomas for the reasons previously discussed. Mass effect is judged by the effacement and displacement of the fourth ventricle and cisternal spaces and by distortion of the brainstem. This is of particular concern when hydrocephalus is already present. If there is no hydrocephalus and a conservative approach is chosen, repeat the imaging relatively early to detect any increase in the size of the hematoma or the development of hydrocephalus; in these patients, acute coma or apnea may develop. Craniectomy is favored above craniotomy in this location.

Epidural Hematomas

Epidural hematomas (EDHs) are usually secondary to a skull fracture that lacerates a meningeal vessel or venous sinus, or that causes venous blood to accumulate from the fracture edges; however, occasionally there are no associated fractures. In infants, EDHs are less common because the dura is relatively well attached to the skull, and the meningeal vessels are not encased and so are relatively easily displaced rather than torn. An EDH is in many ways the most lethal complication of head trauma that is amenable to surgery, with the potential for complete recovery. An EDH may be associated with very little parenchymal brain injury sustained during trauma but may lead to death due to rapidly developing mass effect. Therefore, the critical determinant is the time to surgery. Classically, a lucid interval may occur; the patient recovers from the initial concussive trauma but then deteriorates as the growing hematoma distorts the brain. Overall mortality is about 5% in children, but this depends on the associated findings and presenting condition.⁶

Although an EDH occasionally may be treated conservatively, the indications for this approach are very specific—the requirements are minimal mass effect of the hematoma (maximum thickness usually < 1 to 1.5 cm), an awake patient, close neurologic observation, and repeated imaging. No formal guidelines exist for children, but the adult literature advises removal of any EDH with a volume of 30 cm³ or more.⁶ When the mass effect of an EDH is evaluated, particular attention must be paid to its location, midline shift, and clinical status of the patient (Glasgow Coma Scale score and focal signs).

The typical appearance on head CT is of a medially convex hyperdense collection. Although EDH commonly occurs frontally or on the convexity, occasionally it occurs in the more dangerous temporal fossa and posterior fossa. The choice of scalp flap is determined by the location and size of the hematoma. A conventional large trauma flap is appropriate for large lesions; however, a focused and quick vertical incision may be used for a patient with a localized clot or for a patient who has deteriorated rapidly and for whom emergent decompression is the

priority. The craniotomy for an EDH should be large enough to evacuate the hematoma and cover the area of probable origin. The surgeon must be particularly careful when fractures cross, or are close to, dural venous sinuses. If so, there must be adequate preparation for potential hemorrhage and a plan to control the sinus. Similarly, depressed fractures must be elevated carefully in cases with significant parenchymal injury, lacerated pial vessels, or proximity to venous sinuses. Hemostasis at the end of surgery must be meticulous. The scalp has been traumatized and tends to be inflamed and prone to oozing. Clotting may be impaired. Bleeding bone edges, especially at fracture sites, should be carefully occluded with bone wax. The use of oxidized cellulose and dural tack sutures at the bone edges of the craniotomy, and perhaps a central hitch suture, may reduce the risk for reaccumulation of the hematoma. If these are used, the surgeon must ensure that placing the suture does not cause a subdural bleed. The bone is replaced and secured with plates and screws (► Fig. 55.2).

Subdural Hematomas

A subdural hematoma (SDH) may be acute (hyperdense on CT), subacute (3 to 14 days, isodense on CT), or chronic (more than 14 days, hypodense on CT). However, although the imaging characteristics may vary during this period, many define an acute SDH up to 14 days after injury.⁷ An SDH is usually located over the convexity of the hemisphere but may occasionally be interhemispheric, on the tentorium, or in the posterior fossa.

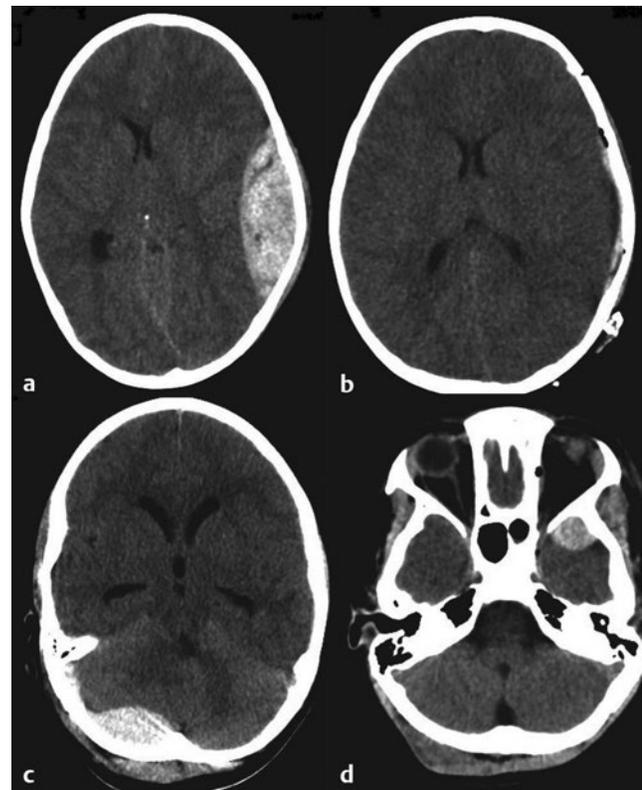

Fig. 55.2 Various epidural hematomas. (a) Left-sided temporoparietal epidural hematoma. (b) Corresponding post-evacuation image. (c) Posterior fossa epidural hematoma. (d) Left temporal tip epidural hematoma.

Acute Subdural Hematomas

Acute SDHs are more likely than EDHs to be associated with underlying brain injury (contusions, brain swelling), so the initial presentation and prognosis tend to be worse; mortality is reported to be as high as 40 to 60%.⁷ The hematoma usually arises from a tear of a cortical bridging vein but may also decompress from a superficially located intraparenchymal lobar hematoma (“burst lobe”). Typically, there is an acceleration/deceleration component to the injury (motor vehicle accidents or falls from a height). Acute SDHs (or acute-on-chronic hematomas, or hematomas of differing ages) in infancy should always raise the suspicion of nonaccidental injury, particularly when there is a discrepancy with the history. SDHs that occur after birth trauma should be considered separately (see below).

The typical appearance of an acute SDH on head CT is that of a crescentic (convex outward), hyperdense clot, often with underlying brain swelling. Over time, the density of the clot decreases; however, a hyperacute clot may also be relatively hypodense. The indications for evacuation of an acute traumatic SDH must be individualized to the patient (age, size and location of the hematoma, level of consciousness and focal signs, associated lesions). However, most clinicians would agree that surgery should be considered for a hematoma with a thickness of more than 5 mm. Official recommendations for adults suggest a thickness of 10 mm or more and/or a midline shift of 5 mm or more.⁷ If the thickness is less than that, surgery is still recommended if there is clinical deterioration.

At surgery, the brain tends to be swollen and hyperemic. The bone flap must be large enough to expose the point of bleeding. If the dura is very tense before opening, it may be prudent to evacuate the clot initially through sequential slits in the dura. Widely opening the dura without control of brain swelling may precipitate the herniation of a congested, hyperemic brain. If the brain is known to be swollen before surgery, the anesthesiologist can take the following measures to assist with the control of ICP: elevating the level of the bed, providing good analgesia and anesthesia, administering hypertonic saline/mannitol at the start of surgery or just before, avoiding hypertension, controlling the CO₂ level, and temporarily hyperventilating the patient when the dura must be opened (at 100% FiO₂). These maneuvers in combination are usually successful in controlling brain swelling, at least for the time period required to open the dura, evacuate the clot, and place an expanded duraplasty. The clot must be evacuated gently under direct vision because sometimes thrombosis has occurred at the point of bleeding but suction of the clot from the vessel may cause rebleeding. This is particularly dangerous when clot beneath the dura, where it is not fully exposed, is suctioned. Caution should be exercised, with gentle suction and wash of the clot. If the brain is swollen, a duraplasty with pericranium or a dural substitute is used to close the dura, and the bone should be left off.

Chronic Subdural Hematomas

Chronic SDHs are most commonly secondary to trauma, ventricular shunts, or surgery. A special consideration is the SDH that occurs after *nonaccidental injury*. The latter condition may present acutely but is commonly seen in a patient with a background of previous injury that has resulted in brain atrophy and bilateral SDH collections with different densities because

the bleeds occurred at different times. The prognosis is often poor as a consequence of multiple episodes of injury, a delayed presentation, and the vulnerability of the young child at presentation. *Anticoagulants* are a risk factor after minor head injury. Subdural collections that develop after overdrainage due to a *ventricular shunt* contain CSF or blood, or a mixture of both. Although these collections sometimes resolve spontaneously, most cause a progressive mass effect or calcify over time. Treatment depends on the size of the collection and the type of shunt used. In general, the drainage of significant collections and upgrade to a higher-pressure valve, programmable valve, or antisiphon device may be indicated.

Chronic SDHs must be distinguished from the benign extracerebral subarachnoid collections of CSF seen in *external hydrocephalus* and the subdural effusions associated with *meningitis*, especially *Haemophilus meningitis*. Nonaccidental injury must also be distinguished from *glutaric aciduria type 1*, a rare metabolic disorder whose radiologic signs may mimic those of the former.⁸

In a chronic SDH, a vascularized membrane develops over the subdural collection as a consequence of the brain's inflammatory response. Repeated bleeds from the vascularized membrane may progressively enlarge the collection. Treatment depends on the underlying condition but may involve a subdural tap through the lateral aspect of an open fontanel, bur hole drainage and irrigation, or placement of a subdural drain or shunt, with correction of the underlying abnormality where appropriate (► Fig. 55.3).

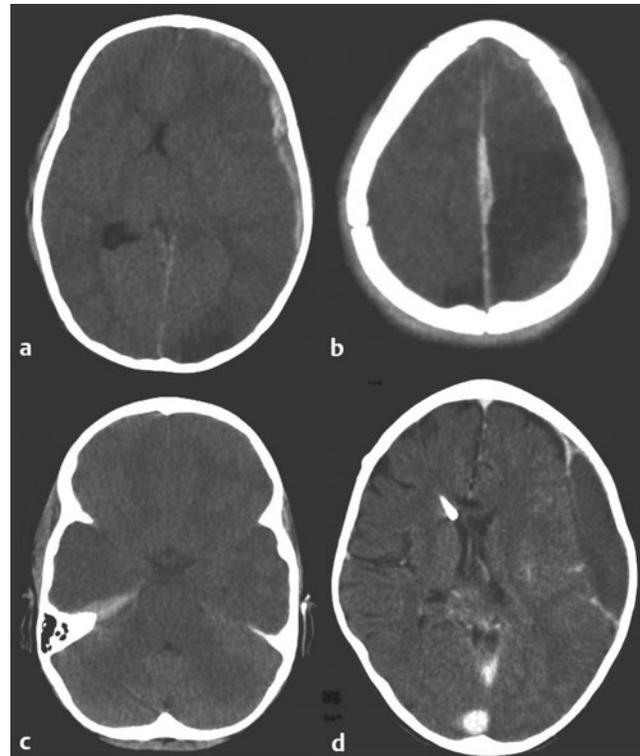

Fig. 55.3 Various subdural hematomas. (a) Swollen brain after trauma, with a left-sided acute subdural hematoma, midline shift, and left occipital hypodensity. (b) Interhemispheric subdural hematoma and bilateral hypodensities. (c) Subdural hematoma on the right tentorium. (d) Chronic subdural hematoma after cerebrospinal fluid overdrainage related to ventriculoperitoneal shunting.

Intracerebral Contusions and Hematomas

There is no clear distinction between contusions and intracerebral hematomas (ICHs) in trauma. Contusions tend to be smaller and mixed with disrupted brain tissue, whereas hematomas are larger, coalesced, more homogeneous collections of blood clot with discrete margins. Intracerebral lesions may be associated with penetrating or blunt trauma. Penetrating trauma is uncommon in children but easily missed. Often, the scalp wound is small, and penetration of the brain is easy because of the thin scalp and skull. The point of skull penetration may be very focal and not easily appreciated on clinical examination (especially if behind the hairline) or plain radiographs. Deep penetration of the brain with a sizeable contusion or track hematoma may be associated with a very small skull defect. Gunshot wounds and assault stabs are obvious mechanisms, but unusual objects may be the cause (e.g., tent peg, nail, pen). Blunt trauma causes focal or diffuse injury. Focal injury is concentrated at the site of impact, at times associated with a contrecoup lesion. Diffuse injury contusions typically occur in the orbitofrontal and temporal regions or in relation to the base of the skull, gray–white interface, corpus callosum, or brainstem. Occasionally, large contusions occur deep in the basal ganglia. Where there are substantial contusions in the brain, the threshold for repeated imaging should be low because “blossoming” of the contusions with increased mass effect may be seen. Sometimes, the radiographic appearance of contused brain may develop only after the initial imaging. The pericontusional area may be similar to an ischemic stroke penumbra, in which tissue is viable but threatened by secondary biochemical and inflammatory changes, so that it is progressively incorporated into the damaged area. In this situation, there is a risk for both low and high blood pressure, both of which may cause progressive enlargement of the contusion by ischemia and vasogenic edema, respectively.⁹

Indications for surgery are more difficult than those for extra-axial hematomas; adult guidelines suggest surgery for (1) frontal and temporal lesions larger than 20 cm³ with midline shift of 5 mm or greater and/or cisternal compression and (2) any lesion of 50 cm³ or more. In reality, factors influencing the decision for surgery should include altered level of consciousness, a deteriorating condition, focal signs, coalescence of the hematoma, location and accessibility of the hematoma, and perhaps increased ICP in patients who are being monitored.¹⁰ The surgical principles are similar to those for an acute SDH. In addition, the corticectomy is chosen to achieve the shortest distance to the lesion and protect eloquent brain. Expansive duraplasty and removal of the bone may be considered for the swollen brain (► Fig. 55.4 and ► Fig. 55.5).

Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage (SAH) is rarely clinically significant. It occurs most commonly in diffuse injury,

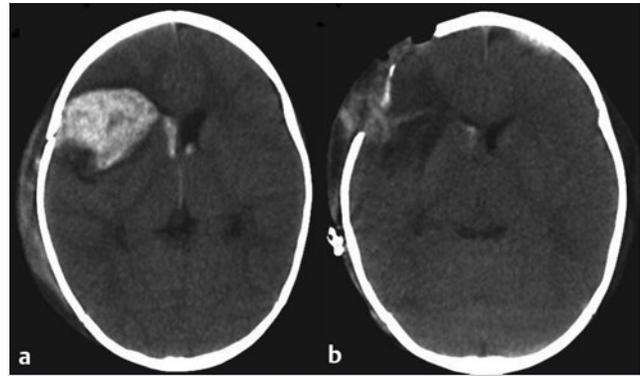

Fig. 55.4 Discrete posttraumatic intracerebral contusion/hematoma. (a) Traumatic intracerebral hematoma in an injury caused by a falling pole. (b) The hematoma has been evacuated.

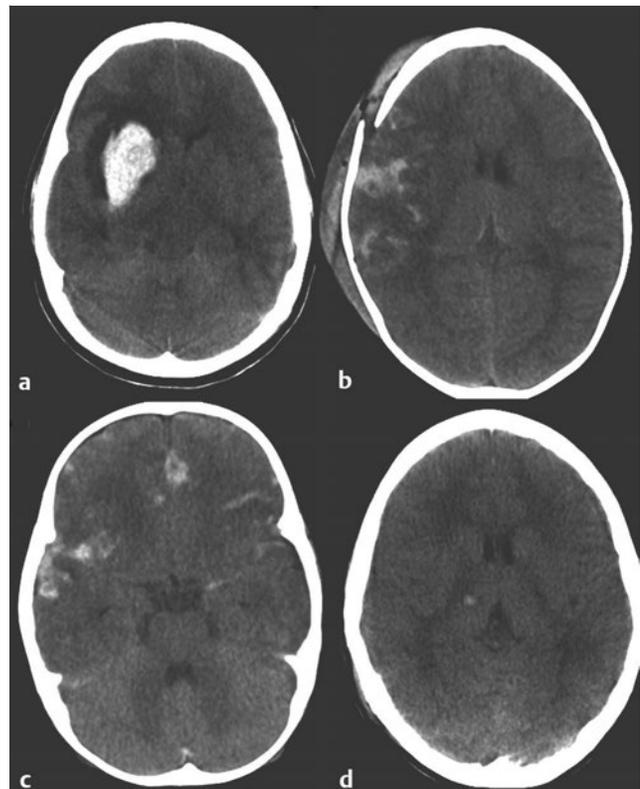

Fig. 55.5 Variations of traumatic contusions. (a) Deep, discrete intracerebral hematoma (motor vehicle accident). (b) Regional, indistinct contusion. (c) Multiple small contusions in the frontal and temporal lobes. (d) Small single punctate contusion in the right thalamus.

usually manifesting as a small amount of blood in the interpeduncular space or in the ambient and quadrigeminal plate cisterns. Some suggest that traumatic vasospasm is relatively common after childhood trauma on investigation¹¹;

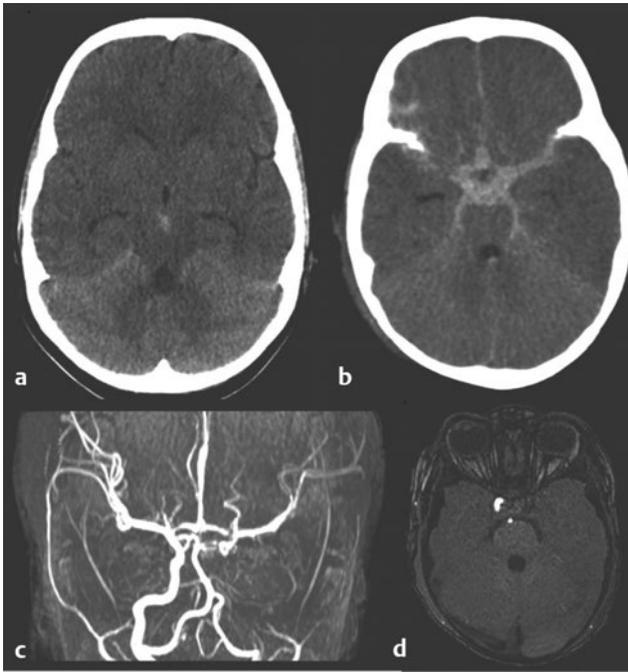

Fig. 55.6 Traumatic subarachnoid hemorrhage. (a) Small amount of subarachnoid blood in the interpeduncular fossa (traumatic). (b) A more substantial traumatic subarachnoid hemorrhage. (c,d) Computed tomographic angiograms of the patient in (b), demonstrating absence of the left carotid.

however, others suggest that this is rare.¹² Unlike in adults, clinical vasospasm appears to be uncommon in children, regardless of the cause. Traumatic SAH rarely causes hydrocephalus in children. If there is substantial SAH (► Fig. 55.6B), the patient should be investigated for blunt cerebrovascular injury with MR or CT angiography.¹³ The management of SAH with nontraumatic causes is discussed below (► Fig. 55.6).

Intraventricular Hematomas

Intraventricular hemorrhage (IVH) may occur after trauma, prematurity (germinal matrix hemorrhage), surgery (ventriculoperitoneal shunt, external ventricular drain, tumor surgery), vascular malformations, and aneurysms. In trauma, IVH is associated with diffuse injury and rarely requires intervention. IVH rarely causes hydrocephalus in trauma but does so commonly when it is associated with other conditions. Management depends on the etiology but in general requires hydrocephalus-related increased ICP. External ventricular drainage reduces ICP and helps clear blood in the ventricles; however, catheters are prone to blockage by blood clot. Other techniques have been tried, including endoscopic washout of the clot and the intraventricular administration of thrombolytics, such as tissue plasminogen activator (tPA). Unfortunately, these do not appear to offer a clear enough advantage to warrant widespread adoption.

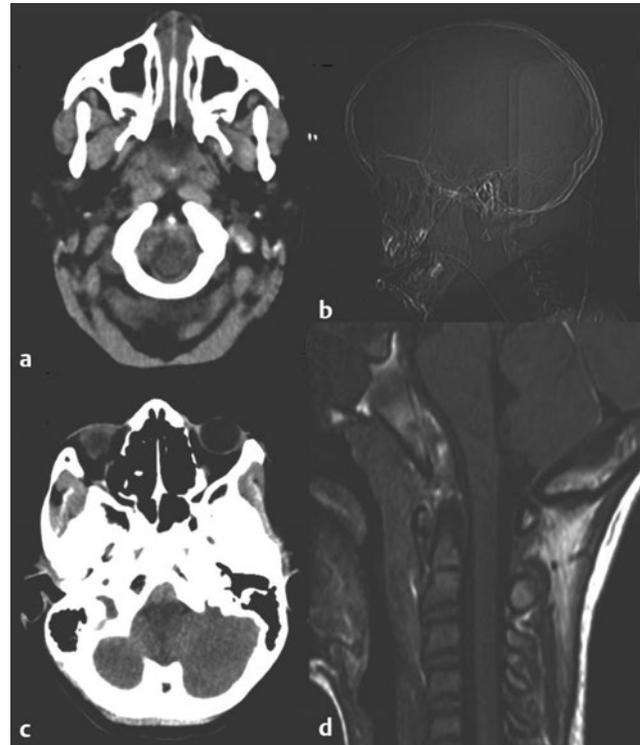

Fig. 55.7 Retroclival hematomas. (a) Axial computed tomographic (CT) scan of the head showing a collection of blood ventral to the lower brainstem. (b) Atlantoaxial disruption in the same patient. (c) CT scan of the head of a different patient showing a more subtle image of blood ventral to the brainstem. (d) Magnetic resonance image of the same patient showing the retroclival hematoma ventral to the brainstem.

Retroclival Hematomas

Retroclival hematomas are unusual trauma-related bleeds, more common in children than adults.¹⁴ The mechanism is unclear but likely related to the anatomical characteristics of the pediatric craniocervical junction, possibly disruption of the tectorial membrane and bleeding from the basilar venous plexus. The hematoma itself rarely requires evacuation, but it is an important diagnosis to make because there may be underlying atlanto-occipital or atlantoaxial disruption (► Fig. 55.7B). Often, the bleed is apparent only on the very lowest axial slices of conventional trauma head CT scans (► Fig. 55.7C), so it should be routine practice to look for these hematomas. When a retroclival hematoma is suspected, MR imaging must be obtained (► Fig. 55.7).

55.4.2 Spontaneous Hematomas

Hemorrhage accounts for nearly half of all pediatric strokes, with mortality as high as 25% and residual disability in 40% of survivors.¹⁵ Management depends not only on the characteristics but also, more importantly, on the etiology of the hematoma (see box “Etiology of Spontaneous Cerebral Hemorrhage in Children (p. 724)”).

Etiology of Spontaneous Cerebral Hemorrhage in Children

- Postoperative
- Vascular malformations
 - Arteriovenous malformations
 - Arteriovenous fistulas
 - Developmental venous anomalies
 - Capillary telangiectasia
 - Cavernoma
- Intracranial aneurysms
 - Saccular
 - Dissecting
 - Infective
 - Posttraumatic
- Brain tumors
- Hematologic
 - Sickle cell disease
 - Thrombocytopenia
 - Hemolytic uremic syndrome
- Coagulation abnormalities
 - Hemophilia
 - Protein C and protein S deficiency
 - Vitamin K deficiency
 - Disseminated intravascular coagulation
 - Hepatic failure
 - Iatrogenic
- Hemorrhagic transformation of an infarct
- Sinovenous thrombosis
- Hypertension
- Neonatal hemorrhage
 - Prematurity-related germinal matrix intraventricular hemorrhage
 - Clotting abnormalities
 - Hemophilia
 - Thrombocytopenia
 - Hemorrhagic disease of the newborn
 - Birth trauma
- Vasculopathy
 - Moyamoya disease
 - Inflammatory vasculitis
 - Herpes simplex encephalitis
 - Other infections
 - Systemic lupus erythematosus
- Other systemic disorders
 - Extracorporeal membrane oxygenation (ECMO)
 - Cancer
 - Substance abuse
 - Congenital cardiac disease
- Idiopathic

In a series of 68 children with spontaneous intracranial hemorrhage, congenital vascular anomalies were present in 42%, hematologic or coagulation disorders in 32%, and an underlying tumor in 13%. Unlike in adults, hypertension is uncommon as a cause of intracranial hemorrhage in children. Management largely depends on the etiology of the bleed, which may or may not be clear. Basic principles are resuscitation, control of ICP,

etiologic diagnosis, and definitive management of the underlying condition.

Definitive diagnosis starts with a good *history*, including any previous intracranial conditions diagnosed, drug history (especially anticoagulants and drug abuse), systemic or genetic conditions known to be associated with intracranial lesions or coagulation abnormalities, underlying illness (cardiac lesions, chronic pulmonary disease, connective tissue disorders), family history, and history of previous trauma. The *examination* includes a full neurologic examination, examination of the heart and chest, and examination for signs of systemic conditions. The complete blood cell count and coagulation parameters must be checked.

Imaging is central to the diagnosis of the underlying condition and surgical evaluation of the hematoma. It is directed by the likely etiology but may include initial head CT for emergent management, CT angiography, MR imaging, MR angiography, MR venography, and digital subtraction angiography. In general, the principles of management are similar to those for trauma but are subject to consideration, investigation, and sometimes primary treatment of the underlying condition.

55.4.3 Specific Conditions Causing Spontaneous Hemorrhage in Children

Prematurity-related ICH and IVH are common in pediatrics, arising from bleeds in the germinal matrix of the brain. A fuller discussion of these is located elsewhere in this book.

Pediatric *aneurysms* are rare, accounting for 5 to 7% of all aneurysms reported. The distribution of ages at presentation is biphasic—aneurysms occur most often before age 2 or after age 10. Children are more likely than adults to present with either IVH or ICH rather than SAH, and also with giant aneurysms or posterior circulation aneurysms. Associated conditions include coarctation of the aorta, fibromuscular dysplasia, autosomal-dominant kidney disease, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum. The pathology of the aneurysm may be dissecting, saccular, infectious, or posttraumatic. Traumatic aneurysms may occur with penetrating injury and fractures of the base of the skull, and dissection may be due to blunt trauma. *Infectious aneurysms*, *infective aneurysms*, and *mycotic aneurysms* are all terms for the immune complex-related false aneurysms that result from an adventitial disruption, mostly due to infectious endocarditis but also to chronic pulmonary disease and intravenous drug abuse. The risk for endocarditis, and so for intracranial infectious aneurysms, is related to the underlying frequency of rheumatic heart disease and congenital heart lesions in the population. Infectious aneurysms may occur at almost any time during the course of the disease—before, during, and after antibiotic treatment for the cardiac valvular lesions. Vertobasilar dissections occur more commonly in boys and present with hemorrhage in about one-third of cases; the others present with headache and vertigo or mass effect.¹⁶

Most aneurysms in children are treated endovascularly. Surgical management of the hematoma depends on its location and size, as well as the primary treatment of the aneurysm. When possible, the aneurysm should be controlled before clot evacuation, should the latter be necessary. If there is no time for

an endovascular procedure (or no expertise immediately available) in a patient whose condition is deteriorating with mass effect, a conservative operation to reduce ICP may be prudent, without an attempt to remove all of the hematoma and risk rebleeding from the aneurysm (► Fig. 55.8 and ► Fig. 55.9).

Vascular malformations also are rare. However, it is estimated that 20 to 40% of all *arteriovenous malformations* (AVMs) or *arteriovenous fistulas* (AVFs) are diagnosed in childhood.^{17,18} Most present with hemorrhage (three-quarters), the rest with seizures or mass effect. Hereditary hemorrhagic telangiectasia should be considered in patients with multiple central nervous system AVMs. Familial AVMs have also been described, unre-

lated to known specific genetic conditions. In children with known AVMs, the annual hemorrhage risk is 2 to 4%, and hemorrhage is reported to be fatal in as many as 25%.¹⁷ *Cerebral proliferative angiopathy* is a relatively new term used to describe vascular malformations that present in predominantly young patients; they are associated with diffuse angiogenesis, small-caliber of feeding vessels and draining veins, and chronic cortical ischemia.¹⁹ A vein of Galen malformation is a choroidal type of AVM involving the forerunner of the vein of Galen, as distinguished from an AVM with venous drainage into a dilated but already formed vein of Galen. Vein of Galen malformations account for about half of all AVMs in children.¹⁸ Many vascular malformations are associated with a dilated vein of Galen but are not classic vein of Galen malformations. They present rarely with hemorrhage, and more commonly with cardiac failure, hydrocephalus, or cerebral venous hypertension. Arteriovenous fistulas are rare, superficial, and fed by pial cortical vessels; about one-quarter are associated with hereditary hemorrhagic telangiectasia.¹⁸ Arteriovenous fistulas may present with a bleed, venous hypertension, cardiac insufficiency, macrocrania, epilepsy, mass effect, or a “sound in the head.” The management of AVMs and AVFs is usually endovascular. Developmental anomalies are extreme variations of normal transmedullary venous drainage that are usually benign but may become symptomatic, presenting with either hemorrhage or venous congestion/infarction²⁰ (► Fig. 55.10).

Cavernomas, or *cavernous malformations*, are estimated to have a prevalence of about 0.4 to 0.8%, which increases with age. Symptomatic cavernomas usually present with either hemorrhage or epilepsy; lesion size and location are the important factors associated with symptoms. The hemorrhage rate in children and young adults varies from 0.2% per patient-year in those with incidentally discovered cavernomas to 8% per patient-year in those with symptomatic cavernomas.²¹ The rate per patient-year is higher than the rate per cavernoma-year, reflecting the higher risk for patients with multiple cavernomas. Multiple cavernomas may occur in familial cases and with certain sporadic genetic mutations. Radiotherapy in early life increases the risk for the development of a cavernoma in later life.²² Cavernomas are notable in survivors of medulloblastomas; however, most of them tend to follow a benign course.²³ The lesions often increase in size over time because of repeated episodes of bleeding and calcification. Head CT and MR imaging show well-demarcated lesions that have a typical “popcorn” appearance, with calcification and evidence of repeated microhemorrhages; the core has a heterogeneous appearance and is

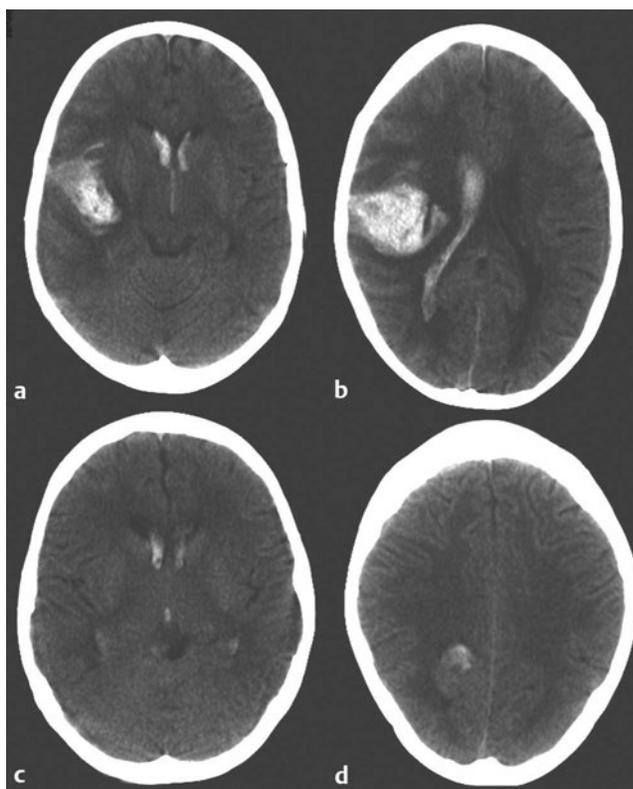

Fig. 55.8 Aneurysmal bleeds in two children. (a,b) Intracerebral hematoma and intraventricular hemorrhage in a patient with an infectious aneurysm, several weeks after the start of antibiotic therapy for infective endocarditis. (c,d) Bleeds due to dissecting aneurysms.

(b) Axial magnetic resonance (MR) image showing a T1 bright lesion with surrounding hematoma and the typical “popcorn-like” character. (c) Axial T2 MR image of the same lesion. (d) Gradient-echo MR imaging sequence demonstrating the blood product.

surrounded by a hemosiderin rim. The gradient-echo appearance is classic. The decision to remove a cavernoma surgically must take into consideration the expected natural history and the likely morbidity of surgery, which is primarily determined by the location of the lesion (► Fig. 55.11).

Tumor-related bleeds depend on the location and nature of the tumor. In general, bleeds are a rare presentation of pediatric intracranial tumors, tending to occur with more aggressive, vascular tumors. Management depends on the clinical presentation, histology of the tumor, mass effect, and location of the clot. Early management targets relief of raised ICP or local mass effect. It may not be ideal to remove the tumor in the same session, so a relatively conservative approach may be indicated to decompress the hematoma emergently. However, it must be

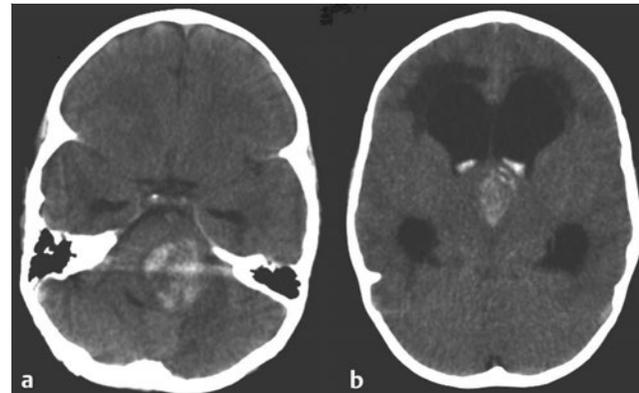

Fig. 55.12 Hematomas within tumors. (a) Computed tomographic (CT) scan of a 3-year-old boy with a spontaneous bleed in a posterior fossa ependymoma. (b) CT of the head of a 5-year old girl showing a bleed within a hypothalamic astrocytoma, with resultant intraventricular hemorrhage and hydrocephalus.

remembered that the risk for bleeding into the surgical cavity is higher with residual tumor (especially if malignant). Intraoperative hemostasis is critical, and pain-related hypertension in the postoperative period must be avoided because it increases the risk for a postoperative bleed. Occasionally, embolization before resection may be suitable for highly vascular tumors, such as choroid plexus tumors, to minimize intraoperative bleeding, especially in very young patients (► Fig. 55.12).

Hematologic Abnormalities

Idiopathic thrombocytopenic purpura is an autoimmune disorder, usually associated with a preceding viral infection. It is one of the most common acquired bleeding abnormalities in children. Intracranial hemorrhage is an uncommon complication but carries a high mortality rate. Surgical management is considered only when absolutely necessary and requires coverage with platelet transfusions. Thrombocytopenia secondary to hematologic malignancies (► Fig. 55.13) presents similar management dilemmas. *Neonatal thrombocytopenia* is discussed below. *Hemophilia A* (clotting factor VIII) and *hemophilia B* (clotting factor IX) are genetic disorders with a relatively high risk for intracranial hemorrhage, especially in neonates, but also following minor head injury in older children.²⁴ Treatment again depends on temporary reversal of the coagulopathy. *Vitamin K deficiency* is discussed below.

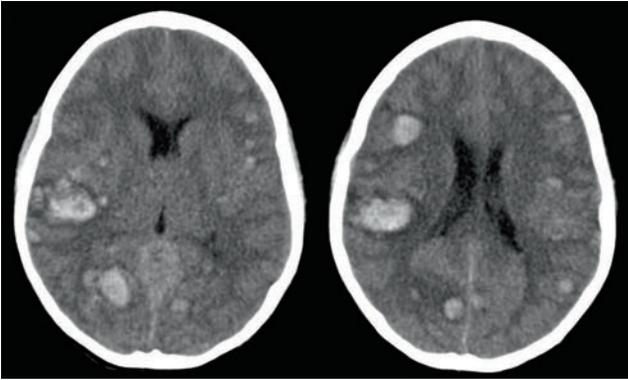

Fig. 55.13 Thrombocytopenia due to acute myeloid leukemia resulting in multiple intracranial bleeds in a child with an acute deterioration in consciousness.

Sinovenous Thrombosis

Thrombosis of the venous sinuses and deep and superficial veins may be associated with several disorders and conditions—dehydration, hypoxia, anemia, malignancies, cardiac disease, renal disease, head and neck infections, systemic diseases (e.g., systemic lupus erythematosus), inflammatory bowel disease, metabolic conditions—and with drugs (e.g., steroids).¹⁷ The presentation depends on the venous structure involved and may include any variety of ICH, SAH, SDH, brain swelling, hydrocephalus, and infarction. Typical imaging shows linear densities in deep and superficial veins on uncontrasted head CT, an empty delta sign as a filling defect in the posterior part of the superior sagittal sinus on contrasted CT (but which can be falsely positive), and absence of flow in the sinus on MR or CT venography.

Extracorporeal membrane oxygenation is used to support infants with refractory respiratory failure, but substantial changes in the cerebral blood flow may lead to intracranial complications, including cerebral hemorrhage, ischemia, and hemorrhagic transformation of an ischemic area.²⁵ Intracranial bleeds in patients with extracerebral *cancer* may result from the effects of chemotherapy, sepsis, and metastasis. *Drug abuse* is a major risk factor for ischemic strokes and cerebral hemorrhage in adolescents, usually due to the pharmacodynamic effects.²⁶ The drugs include cocaine, methylphenidate, and phencyclidine. Intravenous drug abuse also carries a risk for endocarditis and infectious aneurysms.²⁷ Prescription drugs also carry a risk, such as phenylpropanolamine²⁸ and, of course, anticoagulant therapy.²⁹

Neonatal Hemorrhage

Neonatal hemorrhage deserves special consideration because of the different pathologies and presentations. The true incidence of neonatal hemorrhage is not known because many episodes are asymptomatic. For subdural hemorrhage, the incidence may be as high as 8% in otherwise normal terms infants.³⁰ In fact, in one prospective study of vaginally delivered asymptomatic normal infants who underwent MR imaging, 26% had some form of intracranial hemorrhage.³¹ Symptomatic hemorrhage is much less common; an average incidence of about 3.8 per 10,000 live births is reported.³⁰

Traumatic hemorrhage is usually the consequence of birth trauma. Risk factors include instrumented delivery, macrosomia, prematurity, abnormal fetal presentation, and prolonged labor.⁴ Birth trauma may occur in as many as 2 to 7% of all deliveries and is associated with increased mortality and morbidity.³² The pathology spectrum ranges from caput succedaneum and cephalohematoma to subgaleal hemorrhage and subarachnoid, subdural, and intraparenchymal hemorrhage, with or without skull fracture.

Hemorrhage in term infants has a particular predilection for the posterior fossa, often the region of the falcotentorial junction. Deformation of the skull as it passes through the birth canal, especially vertical molding, causes dural tension, with tearing of veins and dural sinuses. In occipital osteodiasis, one particular mechanism, the squamous and lateral parts of the occipital bone separate, leading to rupture of the occipital sinus and direct trauma to the cerebellum.⁴

The pattern of SDHs in infants is different from that seen in older children, and they are more common than previously thought. They are the most common form of intracranial hematoma in term infants and are usually associated with instrumented delivery or cesarian section after failed labor (which may represent an increased risk for difficult labor regardless of the eventual method of delivery). Occasionally, they may be diagnosed in utero or without excessive birth trauma in asymptomatic infants. EDH in neonates is uncommon because the meningeal vessels are not incorporated into the bone and tend to be displaced away from the skull.

Unlike term infants, 80% of preterm infants with IVH have associated *germinal matrix hemorrhagic* infarction; this is primarily a disorder of preterm (50%) compared with term infants (4%).³⁰ *Thalamic or intraventricular hemorrhage* in term newborns is less common. It may arise from several sites—the choroid plexus, thalamus, and subependymal germinal matrix (associated with birth trauma and birth asphyxia)—but in 25% of cases the cause is unknown (it may be cryptic hemangioma of the choroid plexus). Overall, IVH in term infants is reasonably common, but the vast majority of cases are asymptomatic. *Vitamin K deficiency* (hemorrhagic disease of the newborn) may result from an inadequate supply in breast milk, decreased production by intestinal bacteria (antibiotics), malabsorption syndromes or chronic diarrhea, and iatrogenic causes.

Bleeding disorders in neonates may present with intracranial hemorrhage. The most common causes include hemophilia, thrombocytopenia, and hemorrhagic disease of the newborn. Neonatal hemophilia commonly presents with iatrogenic or intracranial hemorrhage, whereas in older children and adults, hemarthrosis is more common. Thrombocytopenia is common in preterm neonates, in whom it may be early (having antenatal causes and usually resolving without treatment) or late (after 72 hours, usually associated with bacterial infection, necrotizing enterocolitis, or congenital infection), and tends to be more severe.³³ It is much less common in term neonates, in whom autoimmune thrombocytopenia is the most important cause.

The *clinical features* of hemorrhage in neonates are different from those in older children. Neonates tend to present with more subtle or nonspecific signs, including irritability and failure to suck. They may also present dramatically, with cardiovascular

collapse, respiratory distress or apnea (especially when the hemorrhage is associated with heart rate irregularities), seizures, and a bulging fontanel. Cranial ultrasound is the first-line investigation in neonates because of the open fontanel, portability, low costs, and absence of radiation. Treatment is directed by the size and location of the hematoma, clinical status, and underlying etiology. The risk for a poor outcome in neonates with symptomatic hemorrhage is high, given their young age and vulnerable brain.

Pearls

- Extracranial hematomas are rarely a surgical problem; however, neonates can bleed acutely into the subgaleal space.
- Control of raised ICP is the first priority in managing intracranial hematomas.
- Time is critical—delay in evacuating an intracranial hematoma may lead rapidly to brain herniation, brain ischemia, and death.
- The principles of management in trauma are resuscitation (especially avoidance of hypoxia or hypotension), early imaging, and surgical evacuation of the hematoma.
- The principles of trauma surgery are a large skin and bone flap, control of bleeders, intraoperative control of brain swelling (anesthesiology), and dural enlargement if there is brain swelling with or without the bone flap left off.
- Vascular anomalies, hematologic disorders, and underlying tumors account for most spontaneous hematomas in children.
- The key to managing spontaneous intracerebral hemorrhage is diagnosis of the underlying condition. The likely diagnosis is suspected from the history and basic imaging, which then determines subsequent management.
- Very large hematomas may present with surprisingly nonspecific signs in young children.

56 Traumatic Brain Injury in Children: Critical Care Management

Michael J. Bell, P. David Adelson, Michael L. Forbes, and Patrick M. Kochanek

56.1 Epidemiology

Traumatic brain injury (TBI) remains the leading cause of death between the ages of 1 and 18 years. In the United States, one TBI has been reported to occur as frequently as every 15 seconds, with one death resulting every 12 minutes. According to the Centers for Disease Control, each year in the United States approximately 1 million infants, children, and young adults sustain a TBI. Of these, 600,000 will come to medical attention and 250,000 will be admitted to the hospital; 30,000 will be permanently disabled and 7,000 will die. Severe TBI in children is responsible for nearly \$20 billion annually in health care costs. International efforts to define the mortality and morbidity burden of severe TBI have proved fruitful. Aggressive prevention efforts and new insights into the pathophysiology of primary injury (moment of impact), as well as the evolution and reduction of secondary injury, continue to show great promise. However, only in the past 15 years has direct scientific inquiry begun to address the question of the optimal treatment of severe TBI in children.

56.2 Development of International Standards: Evidence-Based Management Guidelines and Common Data Elements

In 1996, Bullock and colleagues,¹ using the principles of contemporary evidence-based medicine, published the first guidelines for the management of adult severe TBI. Before this seminal effort, which included the input of international experts, the management of severe TBI in adults was found to be highly heterogeneous, colloquial, and not evidence-based. The panel reviewed studies relevant to the management of head-injured patients and stratified the data based on the quality of evidence. The stratification of existing head injury–related publications according to quality yielded a summary of practical, weighted consensus treatment guidelines and assisted in the charting of directions for future research and funding efforts. Although international acceptance and application were initially variable, independent evaluations of the impact of the application of these guidelines have consistently demonstrated significant reductions in mortality, adjusted length of stay, and costs.^{2,3}

In 2000 and again in 2012, similarly configured panels of pediatric experts were convened to develop consensus guidelines for the treatment of severe TBI in infants, children, and young adults.^{4–23} The developing brain has unique anatomical and cerebrovascular characteristics that warranted the development of independent guidelines. Additionally, the response to trauma of pediatric patients—particularly infants and young children—mandates that they not be treated as “little adults.” The

evidence-based approach was reapplied to the relevant literature on pediatric brain trauma, and “Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents” was published. Three degrees of evidence quality were applied throughout the process (see box “Evidenced-Based Medicine Levels of Evidence in Severe Traumatic Brain Injury (p. 729)”), and three classes of evidence were identified (see box “Classification of Evidence in Severe Traumatic Brain Injury (p. 729)”). In the most recent edition, the pediatric guidelines encompass 15 topics deemed to be imperative to improving outcome. These topics form the scaffolding for this chapter.

Evidenced-Based Medicine Levels of Evidence in Severe Traumatic Brain Injury

- Level 1
 - Sufficient evidence exists that these therapies “should be done.”
- Level 2
 - Sufficient evidence exists that these therapies “should be considered.”
- Level 3
 - Sufficient evidence exists that these therapies “may be considered.”

Classification of Evidence in Severe Traumatic Brain Injury

- Randomized controlled trials completed; may still lack sufficient numbers and have methodologic inadequacies
- Clinical studies based on clearly reliable data; prospective collection with retrospective analysis acceptable
- Retrospective analyses; case series/reports, databases, registries, expert opinion

During the past several decades, it has been recognized that the analysis of clinical studies in TBI has been hampered by a lack of clarity in the definitions of patient characteristics and by inconsistencies in reporting important factors between studies. Specifically, despite the best intentions of authors to fully describe (1) the population under study, (2) the clinical variables collected, and (3) the outcomes that were observed, comparisons of the results of clinical studies suffered from ad hoc editorial decisions made during manuscript preparation. In seminal work on this topic, Lingsma and colleagues took several years to painstakingly combine data from 10 randomized controlled trials (RCTs) and three observational trials in the International Mission on Prognosis and Clinical Trial in Traumatic Brain Injury (IMPACT) study.²⁴ This yielded an analysis of 9,578 patients enrolled at 265 clinical sites that found striking differences in unfavorable outcome rates between centers in the United States and Europe. This led Maas and colleagues to develop common

definitions of various aspects of TBI care, the so-called common data elements (CDEs), to improve the uniformity of defining TBI care and data collection.²⁵ In pediatric TBI, CDEs for acute data collection, imaging, biomarkers, and outcomes were recently published in liaison with the National Institute of Neurological Disorders and Stroke (NINDS), and these elements will be required for future funded clinical trials.^{26–29}

The goals of contemporary pediatric neurocritical care are the early identification and management of surgically evacuable lesions and the prevention of secondary injury. Pediatric neurocritical care strategies for severe TBI have evolved from strategies for exclusively supportive care to those attempting to (1) optimally match substrate delivery and cerebral metabolism with the use of multimodal monitoring, (2) prevent herniation by anticipatory clinical strategies and meticulous nursing care, and (3) target specific mechanisms involved in the evolution of secondary injury with novel or experimental therapy. The re-evaluation of current approaches, the role of newer technologies, and the differences between adults and children will be highlighted.

56.3 Clinical Presentation

The rapid identification of injuries and the assessment of their severity are essential to minimize the risk for undertreating evolving clinical conditions and to ultimately optimize outcomes. The Glasgow Coma Scale (GCS) score³⁰ (► Table 56.1), first described in 1974, remains a critical tool for communicating the severity of neurologic injury after TBI. Hypoxemia, shock, and hypotension all reduce the GCS score. Optimal resuscitation, therefore, is an important prerequisite to assigning the best GCS score. In preverbal children, the GCS score has been modified to allow a score of 5 for the cooing child. The modified GCS score for infants and children (► Table 56.1), although convenient, has not been subjected to extensive peer review.^{31,32} For this reason, the infant GCS score is best applied by those familiar with the management of young children. The best motor score is the most predictive component of the GCS.³³ Additionally, the AVPU (awake, [responds to] verbal, [responds to] pain, unresponsive) scale provides a rapid, albeit crude, assessment of neurologic status. Moreover, the pupillary examination is an

essential aspect of the physical examination to triage children with TBI.³⁴ In a rigorous study of 500 normal subjects, Meyer et al demonstrated that anisocoria of less than 1 mm is clinically unimportant. Sparse evidence exists regarding the prognostic significance of the light reflex. Of note, hypotension, hypothermia, and hypoxemia all confound the pupillary light reflex.³⁵ Optimal resuscitation, therefore, remains the clinical linchpin on which all other assessments, diagnoses, and prognoses rest.

The accurate assessment of the child with TBI is essential to developing a comprehensive care plan that includes the necessary imaging, invasive procedures, and medical and surgical therapies. To date, this has largely been based on the physical findings and the GCS score, as outlined above. In particular, the GCS score combined with signs of acute brain dysfunction aid in the assessment of patient acuity. Clinical signs such as persistently impaired consciousness, a GCS score falling by 2 or more points, amnesia, focal deficits, and evidence of skull fracture all necessitate rapid triage.^{36–39} However, an increasing body of literature is starting to question the assumption that the severity of TBI must be tied to these classic signs⁴⁰ and have suggested that imaging and other factors may add specificity to predicting the need for interventions and outcomes.

56.4 Initial Resuscitation and Prehospital Stabilization

Once a child has sustained severe TBI, rapid assessment, stabilization with triage, and transfer to the highest-necessary level of care are the next steps. The centralization of pediatric trauma-specific resources is the natural extension of this axiom, which, along with patterns of resource allocation, are currently in search of validation. Olson and colleagues⁴¹ published one of the first studies to suggest that the centralization of resources, coupled with an urgency to transfer patients as quickly as possible, might be an incompletely developed model. Their historically controlled review found an increase in trauma-related deaths after the implementation of the Oregon State Trauma System. Patients injured in a rural setting were transferred to a higher level of care, incurring longer transport times. It appears that a system intended to facilitate rapid transfer may have resulted in premature transfer.

Table 56.1 The Glasgow Coma Scale score

	Original	Modified for infants
Best eye response	<ul style="list-style-type: none"> • Does not open eyes • Opens eyes to painful stimuli • Opens eyes to verbal command • Opens eyes spontaneously 	<ul style="list-style-type: none"> • None • To pain • To shout/loud noise • Spontaneously
Best verbal response	<ul style="list-style-type: none"> • No response • Incomprehensible sounds • Inappropriate words • Disoriented and converses • Fully oriented and converses 	<ul style="list-style-type: none"> • None • Grunt, agitated • Inconsolable screams • Consolable, cries • Smiles, coos
Best motor response	<ul style="list-style-type: none"> • No motor response • Extension (decerebrate posturing) • Flexion (decorticate posturing) • Withdraws purposefully from painful stimuli • Localizes painful stimuli • Follows verbal commands 	<ul style="list-style-type: none"> • None • Extension to pain (decerebrate posturing) • Flexion to pain (decorticate posturing) • Withdraws from pain • Localizes pain • Normal movement

Studies of transport decisions after severe TBI in children have been largely retrospective, reporting data on practice patterns. A prospective review of transport decisions comparing children who had severe TBI and were directly referred to an urban Level 1 pediatric trauma center with those who arrived by indirect referral⁴² demonstrated that those who had severe TBI (GCS score ≤ 8) and were directly referred had better survival. These limited data, along with information from adult TBI studies, allowed the first edition of the pediatric TBI guidelines¹⁹ to recommend the transfer of children with severe injuries to centers that had sufficient experience with such patients.

Regardless of transportation from the scene of the injury, several studies have consistently demonstrated increased morbidity and mortality due to failure to correct hypotension and hypoxemia or evacuate mass lesions.^{43–45} Gentleman reported during an 11-year period in England that an approximately eightfold increase in endotracheal intubation yielded a 64% reduction in hypoxic episodes.⁴⁶ This was accompanied by a 40% reduction in the mortality rate and a 45% increase in good outcome. Although the etiology of this improvement may be multifactorial, early, targeted intervention must be the objective of initial therapy.

The success of this study and others further reinforced the importance of reliable, early airway protection.⁴⁷ A provocative study by Gausche and colleagues,⁴⁸ however, added further clarity to the issue. In an RCT, airway management with bag valve mask (BVM) ventilation was compared with airway management with tracheal intubation in the prehospital setting in two urban pediatric trauma centers. There was no demonstrable advantage to tracheal intubation in the only prospective study to date. The severe TBI subgroup analysis (8 of 25 treated with BVM vs. 9 of 36 treated with tracheal intubation) showed that a “good” neurologic outcome was independent of how airway control was accomplished. The subgroup analysis suggests that aggressive airway management after severe TBI may not be essential. Further studies are needed to validate this potentially underpowered result and to address the question over a range of transport times.

The prehospital tracheal intubation of infants and children requires specialized training. There is currently little evidence that aggressive prehospital airway management changes the outcome for children or adults after severe TBI,⁴ and this topic is not explicitly addressed in the newest version of the guidelines.⁴⁹ All trauma patients with supraclavicular injury should be assumed to have cranial and cervical spine injuries until proven otherwise. The initial evaluation of a child after severe TBI begins with a demonstration by an experienced clinician that the child has a patent, maintainable airway. This, by definition, requires that the patient be conscious, alert, and breathing spontaneously. All unconscious patients are assumed to have an obstructed airway requiring immediate airway evaluation. (It will be helpful for readers if we define “unconscious” as not following commands, a Glasgow Coma Score of 8 or less, and not opening the eyes or speaking.)

The relatively larger head, occiput, and tongue of an infant, coupled with the shorter, narrower epiglottis, facilitate airway obstruction if the child’s sensorium has been clouded by a concussive injury. The rescuer must alleviate obstruction immediately (while protecting the cervical spine) to minimize secondary injury due to hypoxemia.

The mnemonic SOAP has been used for the necessary components of an optimal preparation to secure the airway.

- *S (suction)*. For most patients, a flexible 10F catheter will suffice. However, for school-aged children (older than 5 years), we recommend a rigid, plastic suction catheter that can remove particulate debris. This nonkinking catheter allows direct oropharyngeal suctioning. The suction device should be able to provide 30 L/min or greater and a vacuum of 300 mm Hg when clamped.
- *O (oxygen)*. Oxygen (FiO₂ = 1.0) should be delivered immediately to the patient before intubation. Optimal positioning of the patient requires that axial in-line immobilization be maintained to stabilize the cervical spine. The delivery of 100% oxygen facilitates the washout of nitrogen from the functional residual capacity, allowing adequate alveolar oxygenation for safe intubation of the trachea.
- *A (airway)*. Once the patient is properly positioned, ventilation and oxygenation are controlled, and an age-appropriate laryngoscope blade and endotracheal tube have been selected, the patient is ready to be intubated. Secure the endotracheal tube with adhesive tape, but refrain from passing the tape circumferentially around the neck because compression of the cerebral venous return may occur.
- *P (pharmacology)*. The medications chosen must be potent and rapid in their onset of action. The goals of analgesia, amnesia, and neuromuscular blockade must be met rapidly. Ideally, the patient never receives a preintubation positive-pressure breath.

Optimal tracheal intubation of the child with severe TBI requires a cerebroprotective, rapid-sequence induction technique whenever possible. BVM positive-pressure ventilation is to be avoided unless hypoxemia or impending herniation is suspected. One study⁵⁰ suggested that the BVM technique may cause more unintentional cervical spine manipulation than previously appreciated, so great care is advised during manual ventilation.

If a victim of head trauma meets any of the following criteria, assisted ventilation is indicated, with an orotracheal tube as the modality of choice:

- GCS score of 8 or lower
- Decrease in the GCS score of more than 3, independently of the initial GCS score
- Anisocoria of more than 1 mm
- Cervical spine injury compromising ventilation
- Apnea
- Hypercarbia (PaCO₂ > 45 mm Hg)
- Loss of pharyngeal reflex

In children, the recommended route of initial airway control is orotracheal intubation under direct vision.⁵¹ Nasotracheal intubation should be avoided in children with severe TBI for several reasons, including that blind passage of the endotracheal tube around the acute pediatric nasopharyngeal angle makes this procedure an unnecessary obstacle to rapid, physiologic resuscitation and risks injuring the underlying brain in cases of occult skull base fractures or sinus injuries. Orotracheal intubation can be accomplished with a two-person strategy that protects the cervical spine from injury. Although a normal lateral cervical spine roentgenogram is reassuring, it *does not rule out*

cervical spinal injury.⁵² Spinal immobilization must be maintained. One operator accomplishes this via in-line cervical immobilization while the second clinician intubates the trachea. Care must be taken during positioning in preparation for intubation in infants to avoid pressing into the soft tissues of the submental region and accompanying strap muscles because inadvertent airway obstruction will ensue.

56.4.1 Rapid-Sequence Induction

Tracheal intubation, although a life-saving procedure, remains a potent, noxious stimulus that can alter cerebral hemodynamics. Rapid-sequence induction safely secures the airway of an unprepared patient at risk for aspiration of gastric contents. There is minimal resistance to direct laryngoscopy, and the normal responses to having a large foreign body intentionally placed into the trachea are eliminated. Rapid-sequence induction has been repeatedly documented as a safer technique than either nasotracheal intubation or orotracheal intubation without neuromuscular blockade.^{53,54}

In the head-injured pediatric patient, a cerebroprotective rapid-sequence induction strategy should be employed. The sequence involves preparation, preoxygenation, sedation, neuromuscular blockade, and orotracheal intubation. Pharmacologic adjuncts are used to avoid the morbidity associated with hypotension, hypoxemia, intracranial hypertension, and gastric aspiration. The neurologic and hemodynamic status of the patient will direct the pharmacologic strategy. For the victim in cardiac arrest, cardiopulmonary resuscitation should begin immediately. No pharmacologic adjuncts are necessary to secure the airway. For the hemodynamically unstable patient, the combination of lidocaine, fentanyl, and vecuronium (► Table 56.2) is a safe and effective strategy. For the hemodynamically stable patient, the same sequence of drugs in addition to a rapidly acting benzodiazepine (midazolam) can be successfully used. Etomidate has become an effective agent for intubating the head-injured child. In hemodynamically stable patients, doses of 0.2 to 0.3 mg/kg reduce intracranial pressure (ICP) predictably while preserving the mean arterial pressure. Some reports have suggested an increased risk for adrenal insufficiency with etomidate in children with shock.^{55,56}

An alternative in the hemodynamically stable head-injured patient is thiopental, an ultrafast-acting thiobarbiturate. Thiopental reduces the cerebral metabolic rate for oxygen by 45 to 50% within 15 seconds of intravenous injection. This in turn attenuates the intracranial hypertension associated with direct laryngoscopy. The high lipophilicity of thiopental results in rapid cerebral wash-in and equally rapid washout. Therefore, although thiopental is an excellent agent for facilitating the rapid-sequence induction of anesthesia, it must be followed with another sedative–analgesic agent, although its availability in the United States has been limited in recent years. Fentanyl, a short-acting narcotic, and lidocaine reduce the catecholamine surge associated with direct laryngoscopy.

56.4.2 Circulatory Stabilization

The assessment of circulatory function after trauma involves a rapid determination of heart rate, blood pressure, central and

Table 56.2 Drugs for intubation of the head-injured child

Situation	Drugs
Cardiopulmonary arrest	Resuscitation drugs
Hemodynamically unstable	Etomidate, 0.1–0.2 mg/kg Fentanyl, 2–5 µg/kg
	Lidocaine, 1 mg/kg
	Vecuronium, 0.3 mg/kg
Hemodynamically stable	Etomidate, 0.3 mg/kg Fentanyl, 2–4 µg/kg
	Lidocaine, 1 mg/kg
	Diazepam or midazolam, 0.1–0.2 mg/kg
	Vecuronium, 0.3 mg/kg
Evidence of intracranial hypertension (and hemodynamically stable)	Etomidate, 0.1–0.2 mg/kg Fentanyl, 2–4 µg/kg Lidocaine, 1 mg/kg Thiopental, 4–5 mg/kg Vecuronium, 0.3 mg/kg

peripheral pulse quality, skin perfusion, and cerebral perfusion. The identification and correction of airway obstruction, inadequate ventilation, and shock take priority over a detailed neurologic assessment. The first priority in managing the head-injured patient is complete, rapid physiologic resuscitation. Hypoxemia and hypotension must be avoided during resuscitation.⁴³ Children who sustain age-specific hypotension (► Table 56.3) have a worse outcome in comparison with their normotensive peers.^{57,58} Mild systemic hypertension early after TBI may be beneficial and has been associated with favorable outcomes. Although intracranial hypertension and cerebral herniation are the major complications of severe TBI, brain-specific interventions in the absence of signs of herniation or other neurologic deterioration are not currently recommended. Moreover, interventions designed to manage malignant intracranial hypertension (e.g., osmotherapy or diuretics) may be counterproductive to initial resuscitative efforts.

Posttraumatic hypotension must be assumed to be hypovolemic (i.e., hemorrhagic) in nature, but it may also have a component of myocardial depression due to blunt cardiac injury. Blunt cardiac injury, however, is not as common in children as it is in adults.⁵⁹ Fluid therapy in hypovolemic shock is based on the principle of replacement of large volumes as rapidly as tolerated of whatever the patient is losing. The choice of which fluid to use has been a source of controversy. The current recommendation is 20 mL of isotonic crystalloid per kilogram given intravenously. Hypotonic fluid is to be avoided in the initial empiric resuscitation of the brain-injured patient. Subsequent doses of

Table 56.3 Age-specific hypotension

Age range (y)	Hypotension (mm Hg)
0–1	< 65
2–5	< 75
6–12	< 80
13–16	< 90

fluid should be more targeted based on the nature of fluid loss (i.e., packed red blood cells) and should be isotonic.

In summary, there is no Level 1 evidence to fully define optimal prehospital strategies. There is substantial evidence (generally categorized as Level 2 within the guidelines) to suggest that the administration of supplemental oxygen, avoidance of hypoxia and hypotension, early airway protection, and rapid fluid resuscitation are associated with improvements in outcome. Establishing a secure airway with sedative–analgesic agents and neuromuscular blockade and without causing secondary insults is essential in children who have severe injuries. The development of local emergency medical service and hospital evidenced-based protocols for achieving these goals is recommended, along with efforts to improve quality.

56.5 Diagnostic Studies

56.5.1 Computed Tomography

From its first moment of commercial availability in 1973, computed tomography (CT) has had an enormous beneficial impact on neurocritical care. A three-dimensional anatomical map of the brain structure facilitates diagnosis and management decisions in children with severe TBI. This modality, however, is not without limitations and must be utilized as one, albeit important, piece of information. After severe TBI, approximately 15% of adults with a normal CT scan will develop significant intracranial hypertension. Similarly, patients with normal initial CT scans but who have hypotension or abnormal posturing have the same propensity to develop intracranial hypertension as their counterparts with abnormal scans.^{60,61}

For children, there have been several recent advances in the field of imaging. Figg and colleagues found that repeated CT in children who did not have neurologic deterioration was not needed, leading to a new Level 3 recommendation within the guidelines.⁶² More provocatively, after studying a population of more than 40,000 children, Kuppermann and colleagues developed decision rules regarding when imaging is needed based on history and physical examination for children in the emergency department.⁶³ Importantly, this study was intended to limit the exposure of *uninjured children* to ionizing radiation, and it should not be extrapolated to children at high risk for severe injuries.

56.5.2 Monitoring of Cerebral Blood Flow

Techniques for the determination of cerebral blood flow monitoring after severe TBI include (1) stable xenon–enhanced CT, (2) radioactive (inhaled or injected) ¹³³Xe methods, and (3) transcranial Doppler methods.

Stable xenon CT cerebral blood flow measurement can aid in clinical decision making in the management of infants and children with severe TBI. This valuable technique was in clinical use but was temporarily removed from clinical use by the U.S. Food and Drug Administration (FDA). It is once again available as a research tool with investigational new drug (IND) approval by the FDA, but its use is very sporadic at this time. Although not a “monitor” in the sense that it does not provide a minute-to-minute assessment of changes, stable xenon CT blood flow measurement

provides important information about regional cerebral blood flow and its relationship to anatomical disturbances. This information can be readily coupled to nearly all CT scans obtained in the evaluation and follow-up of severely brain-injured infants and children, including the initial scan. The procedure can be completed in a relatively short time (usually within 30 minutes) and is technically contraindicated only if the FiO₂ or mean airway pressure is high (because of the need for the inhalation of 50% xenon gas, which has the effect of inherently increased density) or if the ICP is markedly increased. Serial stable xenon CT cerebral blood flow measurements can be coupled to a physiologic manipulation, such as altering the mean arterial blood pressure or PaCO₂. These dynamic “before and after” studies often provide additional insight into the optimal titration of bedside interventions and further prognostic information. In the largest series to date, we found that unfavorable outcome after severe TBI was associated with early decreases in cerebral blood flow to 20 mL/100 mg per minute or less and loss of CO₂ autoregulation measured with stable xenon CT imaging.⁶⁴ Although a promising modality, it has yet to make an impact on the routine care of children with severe TBI.

Obrist and colleagues⁶⁵ pioneered application of the ¹³³Xe method to assessment of patients after TBI. With multiple detectors, this method can provide information on regional cerebral blood flow and can be used in dynamic studies. Its advantages over the stable xenon CT method are that it can be frequently repeated, and it is a bedside technique. This method has been used in children with TBI to provide important descriptive information. However, its inability to correlate flow with anatomical disturbances is an important limitation.

Transcranial Doppler, a technique that uses sound waves to measure the blood flow velocity in intracerebral vessels, is frequently used to screen for vasospasm after spontaneous subarachnoid hemorrhage. In pediatric TBI, this modality has been used in several research applications to determine autoregulation, CO₂ reactivity, and hyperemia.^{66–68} Given its noninvasive nature, future research may expand the routine role of transcranial Doppler in pediatric TBI.

56.5.3 Monitoring of Cerebral Metabolism

The jugular venous saturation has been used extensively to monitor cerebral oxygen delivery in adults, and there has been recent interest in assessing its utility in children.⁶⁹ Studies in adults suggest that therapies like barbiturates and hyperventilation can be effectively titrated to jugular venous saturation. Gopinath et al reported the association of desaturation below the threshold value of 50% and mortality in adults.⁷⁰ Jugular venous desaturation below this level was rarely the sole indication that urgent intervention was necessary. Technical problems with placement and false desaturation readings are two additional caveats to this technique. Nevertheless, this monitoring tool can provide valuable information to assist in clinical decision making.

Furthermore, transcranial oximetry has been described as a noninvasive technique that may prove quite useful. Dunham and colleagues⁷¹ reported that measurement of the transcranial oxygen saturation (StcO₂) detected cerebral hypoxemia even in

the context of a cerebral perfusion pressure (CPP) of 70 mm Hg or higher in 16% of their nearly 4,000 observations over 6 days in a neurosurgical intensive care unit. Finally, brain tissue oxygen pressure (PbO₂) correlated with cerebral hypoperfusion, GCS score, severity of injury, and mortality. Further studies are needed to confidently and practically import these techniques to the bedside.

56.5.4 Monitoring of Intracranial Pressure and Brain Oxygen Pressure

It has long been recognized that clinical signs like pupillary size, light response, and papilledema fail as early indicators of intracranial hypertension. Most (but not all) patients at risk for the development of intracranial hypertension are identified by CT. ICP monitoring devices provide a window into the global pressure of the brain and impending crises—when the ICP reaches levels that can cause cerebral ischemia or herniation. ICP monitoring can be accomplished with either intraparenchymal or intraventricular devices. The preferred device remains the ventriculostomy catheter, which facilitates the real-time monitoring of ICP and affords the clinician the option of therapeutically draining cerebrospinal fluid (CSF). In the ideal circumstance, infection rates are acceptably low. Currently, ICP monitoring by ventricular catheter is considered the most accurate, inexpensive, and reliable method. The ventricular catheter also affords a key therapeutic option—CSF drainage. Other acceptable methods include parenchymal fiberoptic and microtransducer systems, whereas subarachnoid, subdural, and epidural monitors of any type are less reliable. Although the fiberoptic ICP catheter is useful in cases of severe intracranial hypertension with slit-like ventricles, data drift after 4 to 5 days may limit its use beyond the first week after injury.⁷² Furthermore, currently available fiberoptic catheters are single-calibration devices. Recently, an approach in which both an externalized ventricular drain (for drainage of CSF as a therapeutic maneuver) and an intraparenchymal device (for continuous measurement of ICP) are placed has been advocated.⁷³

Although there is currently insufficient evidence to support an absolute standard regarding when to place an ICP monitoring device, Level 3 evidence^{32,74–79} supports the placement of a device in patients with a GCS score of 8 or lower. ICP monitoring is considered a reasonable option for infants (even those with open fontanelles) and children with severe TBI and a GCS score of 8 or lower. The threshold of when to treat an elevation is currently any sustained ICP of 20 mm Hg or higher, again supported with Level 3 evidence.⁸⁰ Age-specific recommendations are currently not possible until our understanding of ICP, CPP, and the intricacies of cerebral hemodynamics are clarified in coming years. The range of 45 to 60 mm Hg currently represents the closest age-related goals for CPP.⁸¹ The identification of a “herniating pressure” and its relationship to both ICP and CPP remains critical to our understanding of this parameter. Moreover, the insidious nature of cerebral hypoxemia warrants the integration of multimodal measures of cerebral hemodynamics. ICP monitoring was also suggested to be appropriate in adults with severe TBI and a normal head CT scan if hypotension or motor posturing complicated the clinical course. This approach appears reasonable in children as well. The risks versus benefits

of ICP monitoring must be considered in the clinical decisions for patients in whom the complication rate is high, such as those with coagulopathy. Based on recent work with recombinant factor VIIa, this agent may rapidly minimize the risk for bleeding in patients with a coagulopathy after severe TBI.⁸²

Because of the high risk for cerebral hypoxia and/or ischemia,⁸³ the measurement of cerebral oxygen after TBI has garnered intense interest for some decades. Most recently, FDA-approved catheters that measure interstitial brain oxygen (partial pressure of brain oxygen, or PbO₂) have been introduced into the clinical milieu. Several reports have demonstrated some utility in PbO₂ monitoring.^{84–89} A report by Stiefel and colleagues showed that a protocol targeting a PbO₂ of at least 25 mm Hg decreased mortality compared with mortality in historical controls for adult TBI victims. In children, several studies suggest that PbO₂ monitoring may be helpful. Figaji and colleagues demonstrated that the maintenance of conventional management targets (ICP < 20 mm Hg, CPP ≥ 50 mm Hg, PaO₂ ≥ 60 mm Hg, SaO₂ ≥ 90%, and hemoglobin ≥ 8 g/dL) resulted in at least one episode of PbO₂ below 20 mm Hg in 80% of children and episodes of PbO₂ below 10 mm Hg in 32% of children,⁹⁰ and that children with these episodes had an increased incidence of unfavorable outcome in multivariate regression analysis. Steifel and colleagues demonstrated that decreased PbO₂ was associated with ICP and CPP derangements.⁹¹ A decisive study demonstrating that PbO₂ monitoring (or a PbO₂ threshold, more likely) improves neurologic outcome after pediatric TBI has yet to be performed. However, this technology, with relatively low risk and the potential to effect significant changes in clinical strategies, has been adopted within more centers over the last several years.

56.6 Medical Treatment of Elevated Intracranial Pressure

56.6.1 Hyperosmolar Therapy

Basic science support for the impact of osmotherapy is over a century old,⁹² with an ever-expanding variety of agents being introduced into the clinical armamentarium. First mannitol and then various hypertonic saline solutions have been considered an integral part of neurocritical care for pediatric TBI for years despite few definitive trials demonstrating efficacy in improving overall outcome. In fact, like many aspects of TBI care, mannitol administration is so ingrained within standards of care protocols that RCTs comparing mannitol with placebo are extremely difficult to design. It may be that other study designs, such as comparisons of established therapies based on comparative effectiveness research strategies, could play some role in establishing superior strategies. Pathophysiologically, the immediate benefit of osmotherapy in the context of raised ICP is undeniable; an immediate reduction in blood viscosity leads to decreases in cerebral blood volume and ICP via Poiseuille's law. This results in an immediate reduction in ICP, albeit a transient one. Muizelaar and colleagues⁹³ demonstrated that this mechanism (viscosity autoregulation) appears to operate only when pressure autoregulation of the cerebral blood flow is intact. When it is not intact, the decrease in viscosity will be accompanied by an increase in flow and no change in vessel caliber, cerebral

blood volume, or ICP. Note that if a bolus of mannitol is given too rapidly and produces transient systemic hypertension in a patient with defective pressure autoregulation, cerebral blood volume and ICP may transiently increase. More prolonged decreases in ICP are observed after the administration of mannitol and are related to the dehydration of brain parenchyma via an osmotic effect. Theoretically, this osmotic effect should operate only where the blood–brain barrier is intact, although there is some controversy regarding the location(s) of the dehydrating effect of mannitol.⁹⁴ It must be emphasized that osmolar therapy should be carefully titrated with careful attention to the maintenance of a euolemic state. Experimental evidence indicates that a high serum osmolarity (serum osmolarity > 320 mOsm/L) may be associated with renal failure in adults, thus limiting the use of mannitol under these conditions.

Hypertonic (3%) saline has become a popular alternative to mannitol, and an increasing body of literature supports its use to mitigate ICP crises. The start of this effort can be traced back to Peterson and colleagues,⁹⁵ who reviewed their experience with 68 children from 1985 to 1990. Their clinical protocol incorporated conventional therapy with intentional osmotherapy combining 3% saline infusion, furosemide, and mannitol. They showed effective ICP control for the majority of the patients, with no hyperosmolarity complications. Two studies using hypertonic saline solutions were judged to be Level 2 evidence in the most recent guidelines. Fisher and colleagues randomized 18 children to receive 3% normal saline solution or 0.9% normal saline solution to determine the effect of the intervention on ICP (> 2 hours after administration), ultimately finding that the experimental group had decreased ICP and a need for additional therapies.⁹⁶ Similarly, Simma and colleagues tested the hypothesis that 1.7% normal saline solution (administered as a continuous infusion over 3 days) would decrease ICP compared with lactated Ringer solution.⁹⁷ They failed to show an effect on overall ICP but did demonstrate a decreased need for other ICP therapies in the experimental group. Khanna and colleagues⁹⁸ reported their experience in 10 children with malignant intracranial hypertension refractory to conventional therapy. Doses ranging from 0.1 to 1.0 mEq of sodium per kilogram per hour were titrated to achieve a targeted serum sodium level. Targeted osmotherapy resulted in lower average ICP, increased CPP, less frequent ICP spikes, and predictable increases in serum sodium and osmolarity. One child required continuous venovenous hemofiltration. Over time, his renal function was fully restored. Larger, multicenter studies will shed additional insights regarding the optimal use of this treatment modality.

56.6.2 Hyperventilation

The vasoconstrictor effect of hyperventilation on the cerebral arteriolar system has been used in the management of patients with severe TBI for decades. However, contemporary management has veered away from the long-standing “blind” and prophylactic application of hyperventilation in the management of severe TBI. Studies in experimental models have demonstrated that the effects of hyperventilation on CSF pH and arteriolar diameter are short-lived (i.e., vessel caliber returns to baseline in less than 20 hours).⁹⁹ In addition, chronic hyperventilation produces a loss of metabolic (bicar-

bonate) buffer in the CSF, putting the cerebral circulation at greater risk because of hypersensitivity of the vasculature to changes in PaCO₂. Muizelaar and colleagues¹⁰⁰ compared mild versus moderate hyperventilation in adults after severe TBI, showing that moderate prophylactic hyperventilation (PaCO₂ = 26 to 27 mm Hg) was not beneficial and was associated with worse outcome at 3 and 6 months. These findings mirror reports demonstrating (1) early posttraumatic hypoperfusion after severe TBI, (2) widening of the arterial–jugular venous oxygen content difference that can be observed early after trauma; and (3) jugular desaturation that can accompany profound hypocarbia. It is important to recognize, however, that although the prophylactic application of hyperventilation can be detrimental, hypoventilation (leading to hypercarbia) is equally worrisome because of potential increases in cerebral blood flow leading to increased cerebral blood volume and intracranial hypertension. In summary, contemporary neurocritical care generally calls for mild hyperventilation to keep cerebral blood flow as normal as possible except in cases of impending herniation (in which hyperventilation to mitigate cerebral ischemia from brainstem compression can be lifesaving). It is likely that future studies demonstrating the feasibility of titrating cerebral blood flow—with serial measurements of CBF from stable xenon CT scan, extrapolated estimates of cerebral blood flow from PbO₂ monitoring, or continuous cerebral blood flow measurements from invasive devices—may show a role for hyperventilation in individual children after TBI.

56.6.3 Barbiturates

Barbiturates reduce ICP via a coupled reduction in the cerebral metabolic rate and cerebral blood flow, leading to a decrease in cerebral blood volume and ICP. As with other therapies, there have been no RCTs in children to test the efficacy of barbiturate therapy. Two small RCTs in adult TBI victims failed to demonstrate such an effect, but this should not be interpreted to mean that this therapy should not be considered. Goodman and colleagues¹⁰¹ reported an improvement in brain interstitial concentrations of lactate and glutamate accompanying a reduction of ICP in seven adults treated with barbiturates for refractory intracranial hypertension. Pittman and colleagues demonstrated that 52% of children responded to barbiturate therapy during refractory intracranial hypertension.¹⁰² Moreover, Kasoff and colleagues demonstrated that the use of barbiturates in children with TBI caused frequent bouts of hypotension, leading to the recommendation that the use of barbiturates be accompanied by invasive hemodynamic monitoring.⁷⁷ In addition to cardiovascular monitoring, it is recommended that electroencephalographic monitoring be used to assess the cerebral metabolic response to treatment, with the end point of this therapy generally being burst suppression. It is possible that as the use of hyperventilation wanes in the management of children with refractory intracranial hypertension, alternative therapies such as barbiturates will again be used.

56.6.4 Hypothermia

The theoretical benefits of therapeutic hypothermia have been under study for decades; mechanisms like decreased metabolic

demand leading to decreased cerebral blood flow and cerebral blood volume with decreased ICP, alterations in cell death pathways, decreased intracranial hypertension, and others have been postulated. Over time, numerous anecdotal cases and uncontrolled trials have suggested favorable and unfavorable effects. Until very recently, controlled trials of the use of therapeutic hypothermia in human head injury were lacking.

Experimental models of cerebral ischemia and trauma suggest that transient, mild, or moderate hypothermia (32 to 34°C) attenuates excitotoxic neurotransmitter concentrations and the local proinflammatory cytokine response, thereby producing beneficial effects on neuronal recovery and neurologic outcome.¹⁰³⁻¹⁰⁵ Efficacy for hypothermia was demonstrated in adults after cardiac arrest in 2002, spurring interest in extending this therapy to other brain injuries.^{106,107} For adults with TBI, hypothermia has had mixed results. Two RCTs (32°C for 24 or 48 hours) have shown beneficial effects,^{108,109} with decreased seizure frequency, decreased ICP, and transient improvements in outcomes (especially in subjects with admission GCS scores of 5 to 7). A larger, multicenter trial, however, was unable to reproduce the single-center experience.¹¹⁰

In pediatric TBI, a large RCT was performed to test the efficacy of early hypothermia in improving overall outcome.¹¹¹ In this most important study, 225 children were randomized to receive hypothermia (32 to 34°C) or normothermia within 8 hours, were maintained at that temperature for 24 hours, and were rewarmed over approximately 16 hours. No beneficial effect was observed in the hypothermia group regarding outcome, with a trend toward increased mortality and decreased functional outcome (Pediatric Cerebral Performance Category Scale score at 6 months) despite hypothermia leading to improvements in ICP. Several potential confounders were noted within the study (the normothermia group received greater amounts of hyperosmolar therapies, both groups had substantial amounts of hyperventilation). Nevertheless, this study has questioned the utility of hypothermia as applied to all children with severe TBI, leading to questions of whether there are specific populations of children that might benefit from hypothermia.

56.7 Surgical Treatment of Elevated Intracranial Pressure: Decompressive Craniectomy

One of the more controversial areas in the management of both adults and children with refractory intracranial hypertension is the use of decompressive craniectomy. Controlled studies of this modality are lacking in adults and children. Described by Cushing in 1905,¹¹² there has been a resurgence of interest in this approach sparked by laboratory studies and several recent case reports suggesting that decompressive craniectomy may result in ICP reduction and a good outcome in selected patients with intracranial hypertension refractory to medical therapy.¹¹³ Although some have reported disappointing results,^{114,115} De Luca and colleagues reviewed 22 cases and reported with guarded optimism that selected patients may benefit.¹¹⁶ Taylor and colleagues¹¹⁷ showed positive results with very early (within 30 hours of injury) decompressive craniectomy for children

with intracranial hypertension despite optimal management. The marked reduction in postoperative ICP was deemed the primary neuroprotective outcome in this prospective trial. The common thread in all trials that show positive outcomes are young age (younger than 16 years) and early decompression (within 30 hours of injury). The variable outcomes in the collectively published reports underscore the need for a multicenter RCTs to address the question with a larger sample size. More clarity is needed to determine optimal timing, unilateral versus bilateral craniectomy, and the effect of comorbidities on outcomes. Specific recommendations or guidelines for this procedure cannot be made, and like other second-tier therapies for refractory intracranial hypertension (barbiturates, hypothermia, induced hypertension), decompressive craniectomy is used with varying frequency depending on local experience and the discretion of the management team. A seminal study for decompressive craniectomy in adult TBI victims was recently completed, ultimately randomizing 155 adults with severe diffuse TBI.¹¹⁸ Despite successfully alleviating intracranial hypertension, the surgical group unexpectedly had an increased rate of unfavorable outcomes (odds ratio=1.84 [1.05 - 3.24], $p=0.03$). Technical considerations, patient selection criteria, and differences in medical therapies between groups have all been hypothesized as causes for this curious finding.

56.8 Treatment in the Neurocritical Care Unit

Once the initial resuscitation is completed and evacuable intracranial masses have been addressed, the maintenance of physiologic stability and the recognition and management of intracranial hypertension are the priorities. The injured brain has complex metabolic requirements that are poorly understood. Autoregulation of blood flow may be disturbed, and metabolic demands may be either decreased or increased. It is clear, however, that evidence of neuronal death from cerebral ischemia is a common autopsy finding in patients who die after severe TBI. Maintenance of an adequate CPP is the current therapeutic approach that appears to minimize the risk for the development of secondary ischemia. Assessment of the effect of manipulating CPP on cerebral blood flow or other multimodal markers of cerebral metabolism can provide valuable information and aid in the titration of care. Monitoring of the central venous pressure is essential, and assessment of the cardiac output can be valuable in selected cases. The titration of vasopressor or inotropic support may be needed once adequate filling pressure and hemoglobin are confirmed. In some situations, such as the development of neurogenic pulmonary edema, the optimal titration of cardiopulmonary support can be a formidable challenge and a key determinant of outcome. In addition to the importance of CPP, the selection of an optimal threshold for ICP may play a role. Adult victims of severe TBI with an ICP above 20 mm Hg have a poorer outcome than those without increased ICP. Although a large prospective RCT of patients with and without both ICP monitoring and CPP-targeted management has not been performed, a prospective cohort study by Ghajar and colleagues suggested better outcome in adults monitored and treated with CSF drainage than in those without ICP monitoring.¹¹⁹ Several studies have suggested that optimal outcome is

achieved if the neurointensivist responds to even modest levels of intracranial hypertension (i.e., ICP > 15 mm Hg). Further study is needed, particularly in infants and children.

56.8.1 Sedation Analgesia and Neuromuscular Blockade

Sedation and neuromuscular blockade should be used in the setting of intracranial hypertension once appropriate monitoring has been established. Often, in the initial resuscitation, sedation must be carefully titrated. It is difficult to maintain the balance that allows cardiovascular stability, analgesia, and anxiolysis during transport and initial CT yet allows rapid emergence for clinical assessment when a decision regarding surgery or intensive care management may be necessary. Narcotics, benzodiazepines, or small doses of barbiturates are generally recommended for routine use. Recently, for adults, the use of propofol, a nonbarbiturate intravenous anesthetic, has migrated out of the operating theater into the intensive care unit. The utility of propofol in the rapid induction of anesthesia (it works as quickly as thiopental) is surpassed only by its facility in emergence.¹²⁰ The rapid emergence from sedation with minimal confusion has allowed adult neurointensivists to use propofol preferentially over thiobarbiturates and benzodiazepines for sedation after severe TBI. However, reports in the mid-1990s of an idiosyncratic, lethal propofol infusion syndrome led to the re-evaluation of the role of this general anesthetic in the pediatric intensive care unit.^{121–124} Subsequently, propofol infusion syndrome in the deaths of several adults has also been reported.^{125–128} Based on recent recommendations of the FDA, propofol cannot be recommended as a continuous infusion for the sedation of infants and children with severe TBI (www.fda.gov/cder/pediatric/labchange.htm).

Although neuromuscular blockade has been used commonly in the United States, there has been interest in recent years to more clearly define its indications, duration of therapy, and monitoring. It is currently recommended to use neuromuscular blockade after failure to control ICP with optimized mechanical ventilation, sedation, head position, and temperature control. Once neuromuscular blockade is employed, care must be taken to allow therapeutic monitoring with train-of-four testing as well as daily drug holidays.

To our knowledge, no controlled trial of various sedation regimens has been performed in patients with severe TBI. In contrast, Hsiang and colleagues¹²⁹ studied 514 adults with severe TBI and suggested that *prophylactic* neuromuscular blockade was associated with increased length of intensive care unit stay and nosocomial pneumonia. As with most therapies in this setting, careful assessment of indication and meticulous titration of therapy are essential. Finally, intermittent doses of thiopental and/or lidocaine are often needed to blunt excessive rises in ICP secondary to routine patient care maneuvers, such as suctioning.

56.8.2 Cerebrospinal Fluid Drainage

Drainage of the CSF is a direct method to reduce ICP with minimal risks (other than the obvious risk of inserting the ventricular catheter). However, despite widespread use,

studies of the effect of CSF drainage on CPP, cerebral blood flow, and neurologic outcome have been limited, particularly in children. Shapiro and Marmarou described the utility of CSF diversion in 22 children in an observational study, reporting that more than 75% of children observed demonstrated decreased ICP and increased brain compliance (measured with the pressure–volume index) after CSF drainage via an externalized drain.⁷⁹ Fortune and colleagues¹³⁰ compared the effect of ventriculostomy drainage and mannitol in adults after severe TBI and observed similar effects on cerebral blood flow and ICP. CSF drainage was associated with a greater increase in jugular venous saturation than mannitol administration. CSF can be drained intermittently or continuously in children, with threshold values for drainage determined based on the clinical indication. Interestingly, Shore and colleagues¹³¹ suggested that continuous CSF drainage was associated with lower concentrations of a large number of biochemical mediators of secondary injury, such as cytokines, in comparison with intermittent drainage. In addition, a lower ICP was seen with continuous rather than with intermittent drainage. Further study is needed.

56.9 Controversial Issues

56.9.1 Head Position

Head position has been an area of great controversy. Feldman and colleagues¹³² conducted a prospective randomized study of the effect of head position on ICP, CPP, and cerebral blood flow in 22 patients after severe TBI. Both the ICP and the mean carotid pressure were significantly reduced in the 30-degree position compared with the 0-degree position. There was no change in CPP or flow with this intervention. Thus, in general, raising the head to the 30-degree position reduces ICP without deleterious effects on CPP and is preferred. Head elevation and midline position improve jugular venous drainage and possibly CSF drainage and decrease the contribution of these components to ICP, but the effect overall is not dramatic.

56.9.2 Controlled Hypertension

Another controversial area in management relates to the use of induced hypertension to control refractory intracranial hypertension. Whether pressure autoregulation of the cerebral blood flow is intact or defective, hypotension or an inadequate CPP must be rigorously avoided. If pressure autoregulation is impaired, cerebral blood flow is directly related to CPP, and hypotension directly reduces flow. If pressure autoregulation is intact, as CPP is reduced, reflex cerebral vasodilation occurs (to maintain flow), which increases cerebral blood volume and ICP. Note that this latter phenomenon occurs as CPP is reduced within the autoregulatory range.

Based on measurements of blood flow and jugular venous saturation in adults with severe TBI, an optimal perfusion pressure threshold of 60 to 70 mm Hg is generally observed. Currently, a CPP of 50 to 60 mm Hg is the goal for infants younger than 2 years. Based on the relationship between CPP, vessel diameter, cerebral blood volume, and ICP, in selected patients with refractory intracranial hypertension, the induction of arterial hypertension (CPP increased to between 100 and 140 mm

Hg via the infusion of phenylephrine) reduces ICP. However, hypertension reduces ICP only when the pressure autoregulation of cerebral blood flow is intact because it is a hypertension-mediated reduction in vessel caliber that produces the reduction in cerebral blood volume (to maintain a constant flow) and resultant reduction in ICP. In addition, it is unclear what the short- and long-term effects of the applied hypertension are on the development of cerebral edema because the greater hydrostatic pressure applied could exacerbate edema formation. The optimal management of blood pressure after severe TBI requires both extensive monitoring of the involved factors and an in-depth understanding of the mechanisms at work. Induced hypertension is not recommended except as a second-tier therapy and only with careful monitoring. Unfortunately, the use of this intervention is even more complex in the management of infants and children after severe TBI because a single general threshold value of CPP for adequate perfusion is not applicable. Downard and colleagues⁸⁰ have suggested a minimal value of 40 mm Hg for children. In their report of nearly 200 children with severe TBI, all children with a mean CPP of less than 40 mm Hg died. One would anticipate that this value is directly related to age; however, the relationship has not been defined. Management must be tailored to, and carefully titrated in, each individual patient.

56.9.3 Additional Treatment Issues

Seizures are quite common after TBI and should be aggressively treated to prevent complications related to increased metabolic demand during periods of tenuous cerebral blood flow. However, there is little evidence to suggest that the administration of antiepileptic agents prevents the long-term development of epilepsy. Lewis and colleagues found that the administration of phenytoin led to decreased seizure frequency early after TBI in a small series, ultimately judged to be Level 3 evidence.¹³³

Careful attention must be paid to the serum sodium concentration. An increasing body of literature has developed suggesting the harm that may occur if hyponatremia develops in the acute phase of injury. For this reason, children should generally receive isotonic solutions. If hyponatremia develops, it can be attributed to either syndrome of inappropriate antidiuretic hormone secretion (SIADH) or cerebral salt wasting.^{134,135} Care should be taken to determine the cause of hyponatremia correctly because the management of SIADH involves fluid restriction, whereas that of cerebral salt wasting involves the administration of isotonic or hypertonic saline.

The provision of adequate calories and protein is essential during the catabolic response to critical illness, and the beneficial effects of early feeding (either enteral or parenteral) in the critically ill or injured patient are well described. In adult TBI victims, increased administration of calories within the first 7 days was associated with improved outcome in a large cohort study from New York State,¹³⁶ yet similar hypotheses have not been adequately tested in children. In children, an immune-enhanced diet was tested in a small RCT, yet this failed to demonstrate meaningful benefits.¹³⁷ Moreover, the management of glucose administration has received significant attention in the past several years, with several studies demonstrating a relationship between hyperglycemia and poor outcome.^{138,139} It is

still unclear if treating hyperglycemia would alter this relationship, but it appears obvious at this time that care must be taken to monitor the serum glucose closely after TBI.

Finally, glucocorticoids are not recommended in the treatment of patients with severe TBI unless catecholamine-refractory shock develops. Pituitary stalk injury has been reported after severe TBI and can complicate it.¹⁴⁰⁻¹⁴² When corticosteroids are used, a serum cortisol level should be obtained before the treatment dose is administered. This pretreatment level is used to inform the decision to continue therapy.

56.10 Summary

The optimal care of an infant or child with severe TBI requires a multidisciplinary approach in each phase of management. A prompt and vigorous resuscitation including the stabilization and control of ventilation is essential. After the initial evaluation and necessary surgical intervention, multimodal monitoring and the carefully titrated management of intracranial hypertension are recommended to optimize cerebral perfusion, facilitate metabolic homeostasis, and minimize cerebral swelling. Meticulous and optimal neurocritical care management will be the basis for the delivery of future targeted therapies as additional information becomes available on the biochemical aspects of the evolution of secondary neuronal damage and repair.

Pearls

- Management of the pediatric patient following trauma brain injury provides unique challenges due to differences in the basic neurobiology, primary and secondary mechanisms of injury
- The guidelines and common data elements effort provide an overview of our present knowledge base and gap as well as the opportunities for improved communication of future studies and the ability to compare and collate clinical studies going forward.
- Multidisciplinary neurocritical care teams are recommended for the optimal management of these complex often multi-trauma patients for the rapid assessment and rapid institution of treatment
- The goal of acute care management of the brain injured child is to optimize the environment for recovery including perfusion, metabolic homeostasis, neurophysiology, and reparative mechanisms.
- While intracranial pressure monitoring in and of itself is insufficient as a sole therapeutic target, ICP monitors should be considered and placed for any child with a GCS < 8 to assist in the overall management of these patients and treat for any sustained ICP > 20 mmHg
- While available, other types of neuromonitoring are often under-utilized though their addition (i.e.) brain tissue oxygen monitoring, provides an opportunity for a richer understanding of the response of the brain in the acute setting
- Improved understanding of the complex pathophysiology as well as the reparative physiology of the injured brain will lead to further development of new therapeutic options.

57 Rehabilitation and Outcome of Head Injuries

Adam T. Schmidt, Sue R. Beers, and Harvey S. Levin

Traumatic injury is the leading cause of death in children and adolescents,^{1,2} and pediatric traumatic brain injury (TBI) accounts for approximately 40 to 50% of injury deaths.³ Despite efforts at prevention, pediatric head injury remains a significant public health problem in the United States. Of children who survive severe head injury, 50% experience neurologic deficits affecting multiple areas of function.⁴ Although pediatric brain injury was once considered more benign than injury during adulthood,⁵ studies indicate that younger children may be more at risk for impairment than older children, particularly if the head injury is severe.^{6,7} Thus, it is easy to understand why research on the outcome and rehabilitation of children with brain injury continues to receive a great deal of attention by a variety of health care professionals.

57.1 General Considerations Affecting Outcome

57.1.1 Severity of Injury

Not surprisingly, evidence clearly indicates that children sustaining severe injuries have the worst prognosis. Many of these children exhibit long-term deficits in a number of cognitive, psychosocial, and adaptive domains.^{8,9} A unique study of adults who were injured during their preschool years demonstrates the far-reaching effects of severe injury incurred in early childhood.¹⁰ Of the 39 children followed to adulthood, 15 required special school placements for either physical (21%) or mental (18%) disabilities. Despite the fact that the remaining 59% attended “typical” schools and more than two-thirds of this group demonstrated a low-normal or higher IQ, only 23% were able to work full time. This finding suggests that either personality changes or behavior problems, or both, interfered with their functioning as adults. Other studies have indicated that individuals sustaining moderate to severe injuries are more likely to exhibit long-term reductions in quality of life and deficits in a broad range of social skills.^{9,11}

57.1.2 Preexisting Conditions

Although the information on this topic is somewhat limited, a study by Donders and Strom¹² indicated that children with preexisting learning disabilities exhibited a greater than expected drop in intellectual functioning following a moderate to severe head injury when compared with a group that had no history of preexisting learning difficulties. Another case series, by Schmidt and colleagues,¹³ indicated that children with a history of low birth weight demonstrated an attenuated pattern of recovery in terms of verbal memory, academic performance, and adaptive skills when compared with a control group of normal birth weight matched for age, sex, injury severity, and socioeconomic status. Importantly, these groups demonstrated very similar patterns of test performance at baseline, and differences emerged only over time, suggesting a difference in the trajectory of

recovery rather than a preexisting difference in performance between the two groups.

57.1.3 Age of the Child

Current conceptualizations of pediatric head injury suggest that younger age at injury is associated with a less favorable prognosis. In light of this new understanding of the developmental consequences of TBI in children, it is particularly important to consider age at injury in the discussion of outcome. For example, findings from a longitudinal study of very young children (i.e., 4 months to 7 years old at the time of injury) demonstrated not only minimal recovery 6 months after injury but also a reduction in the acquisition of new skills after severe injury.¹⁴ Another study of children ranging in age from 2½ to 16 years at the time of injury found older age at injury predicts better adaptive function for up to 5 years after injury, particularly in the absence of premorbid learning problems.¹⁵ These findings highlight important differences between adult and child outcome research. In children, injury occurs to a developing brain. Thus, Taylor and Alden strongly recommend that the age-related effects of injury and subsequent recovery be investigated with consideration of age at injury, time since the insult, and age at testing. Age and time since insult may take on even more significance when the neuropsychiatric symptoms associated with injury to the frontal systems, such as those commonly seen in children with moderate to severe injury,^{16,17} are the focus of investigation. For example, Levin et al found that younger and older children with *similar* levels of severity and times since injury showed *different* patterns of executive deficits. The differences in injury pattern and recovery of function might be accounted for, at least in part, by the developmental stage of the brain at the time of insult.

57.1.4 Resources of the Family

A child's recovery from head injury may be affected by both neuropsychiatric (e.g., Glasgow Coma Scale [GCS] score, duration of loss of consciousness, de novo psychiatric problems, neurologic status) and what Max et al¹⁸ termed the psychosocial disadvantage factor (e.g., family dysfunction, family psychiatric history, lower socioeconomic status). Noting the adverse impact of pediatric TBI on families, Wade et al,¹⁶ Taylor et al, and Yeates et al completed a series of studies that demonstrated the complicated interactions between premorbid and postinjury family functioning and outcome after TBI in school-aged children.^{19–23} In their 1997 study, this research group showed that perceived family burden and psychological distress are related to recovery in children with head injury.²⁰ Family function before the traumatic injury influenced both behavior and cognitive outcome. These findings were extended in 2004 with a controlled study that was one of the first to demonstrate the importance of family environment in the postacute period. Based on their previous finding indicating the influence of preinjury family function on later recovery, the investigators

controlled for family factors when they assessed outcome. Measures of postinjury family environment (i.e., family economic burden, parental psychological distress, and family dysfunction) were associated with 1-year outcome, with behavior and school function most affected in severely injured children. Further studies by this group have found that the family system continues to influence recovery from brain injury for as long as 4 years after injury.^{21–23} Less than optimal family circumstances exacerbated the adverse effects of TBI on overall behavior, social outcome, and academic skills, but not on cognitive status as measured by neuropsychological tests. However, a series of more recent investigations by Schmidt and colleagues indicates that family socioeconomic status, especially a family's access to financial resources, influences a child's trajectory of recovery in tasks of basic emotion processing.^{24,25} Interestingly, these investigators also demonstrated that many of these effects were more significant in younger children.

The research regarding the influence of family function is not equivocal. Others suggest that the family disorganization frequently noted after pediatric head injury is not necessarily related to dysfunction that was present before the injury occurred.²⁶ Schwartz et al²⁷ investigated the relationship between behavior problems and family function 4 years after injury. Children with TBI who met the criteria for clinically significant postinjury behavior problems were compared with children who had head injury and displayed no such problems. This comparison indicated that although the clinically involved children were more socially disadvantaged, family dysfunction developed only late in the recovery course. Comparison groups did not differ at either preinjury or early (i.e., within the first year after injury) time points, a finding suggesting that negative family outcomes emerged after the head injury.

57.1.5 Mild Injuries

Of the more than 1 million TBIs that occur each year in the United States, mild TBIs are by far the most common, representing at least 79% of all TBIs.²⁸ In recent years, there have been growing concerns regarding the consequences of very mild head injuries (i.e., concussions).²⁹ Concerns have been most notable regarding repetitive mild injuries. Although research continues on the long-term sequelae of these repeated concussive events, some initial data suggest that individuals sustaining three or more mild concussions exhibit long-term decreases in verbal memory skills.³⁰ As many of these mild injuries occur during the course of athletic competition, a major focus of clinical management in these cases is determining when an athlete should return to play. The use of computerized testing for baseline measurement of an athlete's neurocognitive abilities, followed by regularly repeated assessments after a concussion, has gained popularity as a way of guiding and making more informed decisions regarding return to play.^{31–33} Although the use of computerized testing as a sole means of making these decisions has not been universally accepted (see Echemendia et al³⁴ and Mayers and Redick³⁵), it remains a common practice. A major concern with relying exclusively on computerized baseline testing to inform return-to-play decisions is the concern that athletes may attempt to invalidate their baseline performance by intentionally "faking bad" during these evaluations. There is some evidence to suggest that postinjury computerized

batteries, if interpreted with regard to population-based means (as opposed to baseline scores), may continue to provide a valid assessment of postconcussive cognitive symptoms.^{34,36}

57.2 Assessing Neurobehavioral Consequences in the Acute Period

Comprehensive neuropsychological testing is rarely completed in the inpatient setting because the acute consequences of TBI obscure the accuracy of measurement as a consequence of baseline effects. One important exception might be the application of the Children's Orientation and Amnesia Test (COAT),³⁷ a standardized assessment of posttraumatic amnesia. The COAT can be administered serially and is an appropriate component of any inpatient evaluation conducted following a pediatric TBI. Posttraumatic amnesia has been found to be a potent predictor of later recovery from TBI and as such provides useful information for both the neurosurgeon and other rehabilitation providers.

57.2.1 Functional Skills

Assessing functional living (i.e., adaptive skills) following a mild or moderate injury is an important aspect of monitoring recovery, guiding return to play in the case of sports-related injuries or return to school in the case of other, more serious injuries, and helping both clinicians and parents understand when more in-depth evaluation is necessary. Adaptive abilities are those needed to function independently at an age-appropriate level.³⁸ A current challenge in the outcome field is to develop appropriate measures of functional outcome for children. Adaptive abilities or functional outcome in the broadest sense is frequently measured with the Glasgow Outcome Scale (GOS).³⁹ In children, the GOS score depends on return to school as a measure of successful outcome. A child's return to school, however, does not have the same significance as an adult's return to work because legal mandates require schools to attempt to educate all children.⁴⁰ In addition, the broad GOS categories lack sensitivity,⁴¹ particularly when used in a pediatric population, because they fail to consider how the demands on children change across different developmental levels.

A revised version of the GOS, the GOS-Extended (GOS-E),⁴² has promise for evaluating outcomes in pediatric populations but lacks developmental specificity. In a recent study, Beers and colleagues⁴³ modified the GOS-E to create a more developmentally appropriate measure, the GOS-E Pediatric Version (GOS-E Peds). These investigators reported that the GOS-E Peds had good predictive, criterion, and discriminant validity at 3 and 6 months within a sample of children sustaining mild to severe TBIs. The authors argued that the GOS-E Peds would be an appropriate measure to use in future studies assessing outcomes following pediatric head injuries, although few studies have employed this measure to date.

Although not without problems, a more sensitive indicator than the GOS of adaptive competence in children is the Vineland Adaptive Behavior Scales (VABS).⁴⁴ This norm-referenced instrument has the advantage of using a semistructured interview with the parent to measure adaptive skills across the domains of communication, daily living, and social domains and

appears to be sensitive to the changes associated with TBI.⁴⁵ Using serial VABS data, Fletcher et al⁴⁶ showed that age-specific adaptive behavior declined in the year following severe head injury but not after mild to moderate injury. Levin et al⁴⁷ found that functional outcome on the VABS was inversely related to the depth of a brain lesion on magnetic resonance (MR) imaging at follow-up. The VABS is also useful for evaluating premorbid function, particularly in younger children,⁴⁸ and in assessing isolated aspects of adaptive behavior, such as socialization, in the later recovery period. A recent study by Rivara et al⁴⁹ in which the VABS was used indicated that children with moderate or severe TBI exhibited decreases in the ability to participate in age-appropriate activities, communication, and self-care skills, none of which returned to baseline levels at 24 months after injury. Interestingly, these investigators also observed decreases in quality of life at 2 years after injury in children sustaining a complicated mild TBI (i.e., a mild injury with evidence of findings on neuroimaging), suggesting that, at least in some individuals, these injuries may not be as benign as suspected. Other evidence indicates that injury severity and preinjury factors, such as behavioral functioning, adaptive skills, and family environment, can play a role in long-term functional outcomes, even more than 10 years after injury.⁵⁰⁻⁵³

57.3 Neuropsychiatric Manifestations during the Period of Active Recovery

Some of the most common neurobehavioral sequelae within the period of active recovery (i.e., the initial 2 years after injury) from closed head injuries involve deficits in processing speed, memory (especially working memory), behavior regulation, and attention. These difficulties can result in significant behavioral disruption, difficulties in returning to grade-level academic work, and problems with activities of daily living. If deficits in neurocognitive functioning are still evident after the initial postacute period (i.e., the period following the resolution of posttraumatic amnesia and following participation in intensive inpatient or outpatient rehabilitation), referral to a pediatric neuropsychologist for a comprehensive evaluation of cognitive domains is recommended. Specifically, this assessment should be completed before a child resumes full-time academic work. Although a pediatric neuropsychological evaluation is most critical for children who sustained a severe injury, often children with moderate injuries who recover relatively quickly and who typically have little or no need for long-term rehabilitation can also benefit from this kind of thorough postinjury assessment. There are several important factors to consider before a referral for a pediatric neuropsychological evaluation:

- Can the child reliably respond to simple commands and complete basic motor tasks when asked to do so?
- Does the child have sufficient energy to sustain attention and effort for at least 2 to 3 hours of testing?
- Are the child's language and motor skills sufficiently recovered so as to make testing within these domains possible and interpretable? Of note, although continued deficits in either or both of these domains do not explicitly rule out the possibility of neuropsychological testing, deficits do

suggest that referrals should be made to practitioners with specialized experience and training in the assessment of postacute pediatric TBI.

57.4 Areas of Comprehensive Assessment

A comprehensive neuropsychological evaluation involves assessment across neurocognitive domains, including intellectual ability, academic skills, receptive and expressive language skills, visual and verbal memory skills, visual-motor and fine-motor deficits, behavioral and emotional functioning, and attention and executive skills.

Intellectual testing is an important component of pediatric neuropsychological evaluations because it establishes a child's current abilities and provides a baseline level of performance, which is useful in tracking a child's development as he or she matures and as moves farther and farther away from the actual injury. Academic skills are also an important component of an assessment because these skills are frequently robust and may be more resistant to deterioration following a severe injury. As a result, academic performance can help to estimate a child's premorbid abilities. Importantly, because children are continuing to acquire new academic skills, they remain at long-term risk for significant academic delays secondary to a failure to make developmentally appropriate progress. Findings in these two areas are often elaborated on by the identification of a child's strengths, and weaknesses in the cognitive domains discussed in the subsequent sections.

Language skills can be divided into receptive (i.e., the understanding of language) and expressive (i.e., the use of language) skills. Both types of assessment should be conducted in a thorough evaluation in order to determine if additional referrals for outpatient speech and language therapy services are necessary. Language assessment is also an important component of a pediatric neuropsychological evaluation because difficulties with language can often contribute to or exacerbate behavioral and social deficits.

Memory problems, especially difficulties with working memory, are some of the most common problems following a closed head injury. Working memory is the ability to keep information in mind and use it for a specific purpose. For example, working memory is required when someone gives you directions on how to get to a specific room in a building you have never visited before. Because working memory is mediated by structures within the frontal lobe, specifically the left dorsal-lateral prefrontal cortex, it is extremely vulnerable to TBI. Deficits in working memory can lead to problems with everyday behaviors, such as compliance with medication. Although working memory problems are common after TBI, long-term verbal and visual memory difficulties can also arise because these functions are largely mediated by temporal structures, such as the hippocampus, which are structurally and metabolically vulnerable.

Problems with processing speed and motor control are frequent following pediatric TBI. Deficits in these domains can lead to problems in efficiently carrying out academic and adaptive tasks. Measures of processing speed are some of the most sensitive to neurologic dysfunction and should be incorporated in any thorough assessment of neurocognitive skills.

Executive deficits are also very common following pediatric TBI and are related to many of the behavioral difficulties discussed below. Executive functions are a wide range of neuro-cognitive skills and include the following: initiation of activity (i.e., the ability to begin meaningful motor or cognitive tasks); sustaining (i.e., the ability to persist in cognitive or motor tasks that have been initiated); shifting (i.e., the ability to change focus when necessary in order to change strategy or carry out another procedure); and inhibiting (i.e., the ability to withhold a response and/or regulate action as is appropriate for the situation). Because many of these abilities are mediated through structures in the frontal lobes, they are exceptionally vulnerable to closed head injuries. Moreover, because of their protracted development, children may not fully express the extent of the damage they have sustained until the demands on these skills increase as they grow older.

Although traumatic head injury often results in physical impairment, more problematic consequences involve the individual's cognition, emotional function, and behavior. These cognitive, emotional, and psychosocial deficits are frequently referred to as the neuropsychiatric sequelae of brain injury and are a significant cause of disability. Personality and behavior changes following closed head injuries are common manifestations of moderate and severe injuries. Often, these changes in behavioral functioning result in a diagnosis of a novel-onset psychiatric disorder. In a series of investigations, Max and colleagues⁵⁴⁻⁵⁶ demonstrated that upward of 45% of all children sustaining a TBI exhibited novel-onset psychiatric disorders at 3 months after injury. Furthermore, these investigators showed that from 60 to 80% of children sustaining a severe TBI exhibited signs of novel-onset psychiatric disorders.^{54,56} Max et al also suggested that severity of injury, lifetime psychiatric disorder, family psychiatric history, preinjury family function, socioeconomic status, and preinjury intellectual function contributed to, but could not account for, the increase in novel psychiatric diagnoses following injury. A recent follow-up to these initial investigations indicated that nearly half of all children sustaining a TBI exhibited a novel-onset psychiatric diagnosis at 3 months after injury and that personality change and externalizing disorders occurred significantly more frequently in the TBI group than in the orthopedic control group.

57.5 Late Effects of Pediatric Traumatic Brain Injury

As the devastating consequences of TBI in childhood have become better understood, more studies have undertaken what has become known as research into the late effects of TBI. This body of research provides important information for neurosurgeons because it informs them regarding the cognitive prognosis after TBI. This is particularly important for children, who by definition will continue to engage in challenging cognitive pursuits for years after injury. It has been our experience that neurosurgeons, who provide the first line of treatment after TBI, are sought out by families for treatment recommendations sometimes years after the acute injury period, when heretofore unappreciated cognitive problems become more apparent.

57.5.1 Intellectual Abilities
